PURPOSEFUL SPLINTING FOLLOWING INJURIES OF THE HAND

SUMNER L. KOCH, M D, F A C S., and MICHAEL L. MASON, M D, F A C S.,
Chicago, Illinois

NO discussion of the importance of rest in the treatment of injured hands and of methods of securing it would be complete without an acknowledgment of our indebtedness to the teachings of Hugh Owen Thomas, and it is fitting to remind ourselves again of the extent of that obligation

The story of Hugh Owen Thomas goes back more than 200 years when a dark complexioned Welsh boy,¹ Evan Thomas by name, began to show a special aptitude for caring for the sick and injured animals about the farm. As he grew older his reputation spread, and, reversing the procedure of the famed Dr. James Doolittle, who found animals more to his liking than humans, Evan Thomas gradually developed a practice among the farmers of the countryside, a practice which eventually extended over North Wales and neighboring parts of England. On his death, in 1814, a tablet was erected to his memory

"... who, in humble life, without the aid of education or any other advantages, by an extraordinary gift of nature, acquired such a knowledge of the human frame as to become a most skilful Bone-

setter, whereby he rendered himself pre-eminently useful to his fellow-creatures"

Evan Thomas was followed by five sons who carried on his work. Of these, Richard, considered the most skilful, had three sons and four daughters. Except for the eldest, Evan, they carried on the family tradition in their own neighborhoods. Evan at the age of 19 went to Liverpool to seek wider fields for his talents. He began by treating the injuries of his fellow workers in the foundry where he had found an opportunity to work, and so successful was he that he soon was able to set up in practice as a bonesetter. He developed an extensive following among the dock workers and laborers of Liverpool. Here, in 1832, he married a Miss Roberts, and here his five sons were born, of whom the eldest, Hugh Owen Thomas, born August 23, 1834, is our hero.

Hugh Owen was a silent lad of rather frail physique, but an ardent student and a lover of books and nature. An intellectually gifted and greatly loved mother and a thoughtful, kindly schoolmaster were potent factors in developing the idealism, the stern sense of duty, the constant self criticism and unwillingness to be satisfied with any achievement short of perfection, the love of poetry and music which were outstanding characteristics of the boy and man.

From the Department of Surgery, Northwestern University Medical School

¹There is an oft repeated legend that Evan Thomas was of Spanish descent, the older of two brothers, sole survivors of a shipwreck on the rocky coast of Anglesea in Wales

HUGH OWEN THOMAS
1834-1891

ischium. with suitable instruments the arm stems are cut and the ends introduced into the patient's boot. The whole operation is complete in less than five minutes. The boot has been prepared beforehand by having a tube placed in the heel and a vertical V-shaped gap cut out from the back of the upper while the front of the boot is slit up to the toe—all these preparations being essential to avoid friction. This, as Thomas put it, takes less time than it does for a smith to 'blow up his fire.' The next patient may be a case of intestinal obstruction who is visited five or six times a day. And so the round went on until breakfast, which consisted of a cup of tea and a couple of bananas. The meal rarely lasted for more than ten minutes, but he always found time to relate any comic adventure that may have occurred on the round, and to glance at the more important items in his morning paper.

"From nine until two he was at work in his room, where he met with every variety of case both medical and orthopaedic. During the morning he saw between thirty and forty patients, prescribed and dispensed medicine for them, dressed their wounds, reduced their fractures and dislocations, and gave each one his individual attention. Long experience on the surgical side had enabled him to make a rapid diagnosis and to ask only those questions which had a direct bearing on the case.

"His methods of examination, although rapid, were very gentle. He had wonderful knowledge of the movements that give rise to pain and of the value of an accurate grip in steadying muscle and supporting a limb. Whenever he had to handle a fracture he persuaded the patient to abstain from all effort, and to leave the muscles slack, knowing full well how often pain is self-inflicted.

"There was hardly a morning without one or two cases of fracture, and these were always expeditiously dealt with without anaesthesia.

"The equipment of the establishment in Nelson Street was such that no outside aid was needed. There was a blacksmith at work in a smithy, a saddler finishing off the various splints, and duties of others were the making of adhesive plasters and bandages, and the preparation of dressings. There were splints of every size to suit any possible deformity that might appear or for any fracture that might have occurred. No matter from what distance a patient came, no matter whether the affection be spinal caries, hip disease, or fractured thigh, he was always able to return home in an hour or so, most accurately fitted with a simple and appropriate splint.

"At half-past two people were seen at their homes without delay, for at 4.30 he must be back at Nelson Street.

"His last meal finished he hurried from the table to see his evening flock who continued to come until eight o'clock. Although most of these were Club members quite a number of them were surgical cases, but the patients had more confidence in him than in hospitals. In spite of his strenuous day he is bright

and cheery, for he loves to chat with the working man on the character and scope of his work. Usually at eight he made his last round, confining his visits to those cases critical in themselves, or interesting from the point of view of investigation. It was always interesting because compound fractures and intestinal obstruction were often encountered.

"From nine-thirty to twelve he either worked in his lathe room, which was fitted with the most modern machinery, making new surgical instruments or repairing old ones, or he would find his way to the library to read and write.

"Thus, then, presented an ordinary day's work, and to anyone who knew Thomas, with his frail body and anxious mind, entering whole-heartedly into his patients' troubles and always unsparing of effort, it is a marvel how he could continuously work at such pressure for over thirty years—for it must be remembered that he never took a holiday. During all these years of work he was only away from home some six nights, and even on Sunday mornings he had his free clinic when nearly two hundred cases, many of them of great interest, collected from all parts. It was a great scene, and surgeons who were present never ceased talking of the marvels they had witnessed, for Thomas was years ahead of his time and the results of his treatment of fractures and tuberculous arthritis seemed then little less than miracles.

"He used to long for Sunday evenings, which he always devoted to music. His wife sang while he played the flute. These evenings gave him intense delight, for he was passionately fond of music and knew all the operas well, but the night nearly always closed with Welsh airs. In later years when he, as he put it, got 'too tired to blow' he went to bed early and read, while his niece played for him, and before he slept he always called for 'The Dead March in Saul.' He possessed three most beautiful silver flutes, and it is interesting to note that he specially designed some of the machinery of the stops to simplify the movements."

For thirty years he kept up this strenuous pace, happy in his work and in his home, presided over by his one confidant, the gracious and beautiful Elizabeth Thomas. Then, exposure to cold while on a consultation in a neighboring town, pneumonia of brief duration, death—January 6, 1891.

Thomas' claim to enduring fame is securely based on his logical and successful methods of treatment of disease—methods which were unknown to or unrecognized by his contemporaries, but which today are accepted as sound and correct. At the very basis of his treatment was the principle of maintaining complete rest of injured and inflamed tissues. Not only did he insist upon rest for injured and

From the age of 13 to 17 he attended the college at New Brighton, and subsequently was apprenticed to his maternal uncle, Dr Owen Roberts, surgeon to the Workhouse Infirmary at St Asaph. This association with a stimulating personality, a physician with an extensive practice and a scholarly mind, was another fortunate opportunity for this earnest young student.

Eván Thomas, the silent serious minded father wisely and generously decided that his sons should have a medical education and become qualified practitioners. Wisely, because the constantly increasing friction with the medical profession and the handicaps under which he himself labored as a result of his limited medical training made him realize that the opportunities for the bonesetter were steadily diminishing, generously, because he must have foreseen that eventually it might mean a parting of the ways between the unschooled bonesetter and the sons educated in the most advanced medical institution of his day. Such a parting from his eldest son eventually came, with sorrow and unhappiness for both.

At the age of 21 Thomas entered the University of Edinburgh. Symes, Spence, Simpson and Goodsir then held professorships, Lister was house surgeon to Symes. There in rooms on the top floor of one of the tall houses so common in Edinburgh, on an allowance of ten shillings a week, he lived during the two years of the prescribed medical course. Nothing impressed him so much as the number of amputations constantly performed for inflammation and diseases of the joints—conditions he had seen so often successfully managed by conservative treatment in his father's practice.

After two years at Edinburgh, twelve months at University College in London and a period of study in Paris he joined his father in practice at Liverpool. Before two years had passed the parting of the ways came and in 1859 Hugh Owen set up in practice for himself at 24 Hardy Street.

Soon he was as busy as his heart could wish. A number of clubs and organizations of work ingmen chose him as their medical officer. In 1866 he was compelled to seek larger quarters and moved to the house at 17 Nelson Street—

the house which has become almost a shrine to every man interested in the surgery of the extremities, the bones and joints. To it he added consulting rooms and a workshop, the latter fitted with every possible appliance for fashioning the splints which played so large a part in his treatment of injuries and diseases of the bones and joints.

His nephew, Sir Robert Jones, who joined him as an apprentice at the age of 15, has left this graphic picture of the man and his work.

In appearance Hugh Owen Thomas was a striking figure. He was thin and pale, about five feet four in height. His features were refined and clear cut with an intellectual forehead which receded slightly and dark grey eyes which were capable of great expression sometimes sad and thoughtful but often alert and full of fire. His slight moustache was dark and his spare beard pointed. He always wore a closely buttoned black frock coat and a peaked cap to shelter his tender eyes from the light. His manner had been described as brusque but it was not so. He was quick and abrupt and fired his questions and answers briskly but he never repelled. He was loved by children. Always a good listener and most tolerant of criticism he had no patience with dogmatic fool.

A personal sketch would not be complete without an average day's work from early morning till late at night. At six o'clock in the morning he was mounted in a dog cart which had been built by his own smith to his own design on his own premises. He had a list of ten or twelve addresses to be visited before breakfast. It often happened that when he knocks at the door usually with his bare knuckles an empty milk can was handed to him. But as a rule they knew his knock. The patient may have a broken leg, intestinal obstruction or pneumonia. There was always time for a cheery word of advice and admonition. If it was a broken thigh the extensions might want tightening, pressure pads adjusted and many warnings were sure to be given to the household that no bandage was to be meddled with. Another house and he might find that the bandage had been loosened in a case of Pott's fracture. The surgeon stormed and the patient was immediately penitent. He was no longer to be trusted, however, so the bandage is reapplied and a large pin fastens it, but before the surgeon leaves a large blob of sealing wax covers the pin and with a signet ring removed from his finger it is sealed with the initials "HOT." Another visit and Thomas might be seen carrying a boot in one hand and a box containing enormous cutting shears in the other hand. He is about to transform a bed splint into a caliper in a case of tuberculous knee for the time for walking has come. The bandages are undone and the ring of the splint is pressed hard upon the tuberosity of the

of its own weight and because of the injury of tendons and joint capsules into volar flexion—all cry for support in a position which relaxes the injured tissues, and yet the application of a splint is not considered.

Failure to recognize the importance of rest and relaxation of injured tissues is not limited to senior medical students. The house officer sees a patient with extensor tendons of ring and little fingers divided over the middle of the metacarpus. He sutures the tendons, closes the wound and bandages the hand. The idea of a simple splint to relieve tension on the sutured tendons (Fig 1) does not occur to him. The orthopedic resident late in the day sees a nurse who has just sustained a glass cut over the dorsum of the metacarpophalangeal joint and who cannot extend the thumb. He realizes that the extensor pollicis longus has been divided, but bandages the hand and tells her to report to the chief in the morning. The idea of a splint to relax the muscle whose tendon has been divided does not occur to him. The attending surgeon operates upon a patient with radial nerve divided at the middle of the arm. He sutures the nerve and tells the house officer to close the wound. A splint to relax the paralyzed extensor muscles (Fig 2) is forgotten and the patient is discharged from the hospital a week later with a healing wound but a hand limp in volar flexion. A general surgeon sees a patient with division of flexor tendons and median and ulnar nerves on the volar aspect of the wrist. He sutures the tendons and splints the part with wrist and fingers completely extended. If he glanced at his own hand at rest on the table or considered the position of the fingers when relaxed he would realize that complete extension of the fingers puts tension on the flexor tendons and muscles, and that if he immobilizes the fingers in such a position after suture of the flexor tendons either the sutures will give way or they will cut through the tendons and permit complete separation of the sutured ends.

The cases cited illustrate some of the important indications for the use of splints in the treatment of injuries and infections of the hand, but the purposeful use of splints involves still more than the well recognized principle of rest of injured tissues. Of equal

importance with the care of tissues which have suffered a direct injury is the constant and prolonged relaxation of muscles whose nerve supply has been divided. The return of function, which one anticipates as regenerating nerve axons again grow downward into paralyzed muscles, becomes practically impossible of attainment if complete loss of elasticity and muscle tone has resulted from constant overstretching of paralyzed muscles by unopposed antagonists. A different but long recognized application of purposeful splinting is its employment so as to produce tension upon scar tissue for prolonged periods of time—particularly scar tissue that involves muscles, tendons and joint capsules. The subject of purposeful splinting can be presented to best advantage if the cases considered are grouped in accordance with the character of the injury and the anatomical structures chiefly involved.

I INJURIES AND INFECTIONS OF THE SOFT PARTS —SKIN, SUBCUTANEOUS TISSUE, MUSCLES, JOINT CAPSULES

The relief from pain that follows immobilization of injured soft tissues is well exemplified by the rapid improvement that follows splinting of the hand and wrist following a simple sprain. A patient falls on his outstretched hand, or he wrenches the wrist in

Fig 1 A simple aluminum splint to support little and ring fingers in extension and relax their extensor tendons. A crescentic piece is cut out on the radial side so as to eliminate pressure on the thenar eminence, the forearm portion is made concave so as to lie smoothly on the volar surface of the forearm.

inflamed joints, but for injured and inflamed bones, soft tissues, intestinal tract—for any tissue that was involved in injury or infection. With his recognition of the importance of rest he combined a mechanical genius and ingenuity for developing simple and effective methods of securing it, and an unwillingness to stop until he had made as perfect as possible the splint or device or method which would make certain of securing the desired rest.

Many factors conspired to prevent him from gaining the hearing and the audience he deserved. Most of his publications were privately printed and distributed. He had no hospital appointments or teaching affiliations. The antagonism of the members of the medical profession, many of whom considered him simply a bonesetter, his uncompromising attitude toward opponents and critics who knew little of his work, his lack of regard for medical authority, his naturally shy and retiring disposition, and, perhaps, most of all, the fact that he was so completely happy and so completely engrossed in the little world that centered at 11, Nelson Street, all conspired to deprive him of the hearing and recognition he deserved so well. It was the good fortune of the medical profession and the world of suffering humanity that he should have left behind him an able and trained protagonist, Robert Jones, who made the medical world conscious

of the character and importance of his teachings.

Today the name of Thomas is associated in our minds chiefly with the famous hip splint and knee splint, described so carefully in his book, *Diseases of the Hip, Knee and Ankle Joints*. It is often forgotten that he was a general practitioner, interested in every phase of medical work. His treatment of intestinal obstruction was far in advance of his time. His regime of simple feeding and intestinal rest in the treatment of typhoid fever is accepted today as an essential part of the management of a disease which until only 25 years ago was the scourge of cities and armies. He was an expert lithotomist. His first publication was upon fractures of the jaw. So wide a field of medicine and surgery did he illuminate by his teachings and practice.

Earnest, honest, clear thinking, ingenious, devoted to his home and his work, beloved by the poor of Liverpool who gathered in thousands at his funeral, stirred to their very depths by an emotion that found expression in passionate sobs and tears, as they lined the streets or pressed forward to gaze into the open grave,¹ this little man of unquenchable fire and indomitable energy stands out as one of the truly great and wholly admirable figures of nineteenth century medicine.

¹ Lancet 1861: 174

THE importance of rest in the treatment of injured tissues has been stressed by many surgeons since the time of Larrey.¹ The beginner in surgery recognizes its importance in the treatment of fractured bones. By a curious inconsistency, probably due only to failure of attention, he does not realize that rest for contused and lacerated soft tissues is just as essential if healing is to take place promptly and with a minimum of scar tissue formation.

A patient comes into the clinic with a crushed hand, because of the injury sustained two weeks before, the skin over a large part of the dorsum of the metacarpus has become necrotic, the extensor tendons are exposed and partially necrosed. As each turn of the bandage is unwound he grimaces with pain. When the wound is exposed the students are asked in turn what should be done for the patient. One says, "Warm wet dressings to combat the infection", another "Dakin's solution", another, "A skin graft when the infection is cleared up" etc. No one thinks of immobilizing the hand and relieving the constant pain which results from every movement of inflamed and injured tissues. The patient's facial expression, his apprehension at every touch, the position of the hand itself—falling

¹ Dominiq. — J. N. Larrey (1766-1813), the great French military surgeon of his time, secured in the Napoleonic wars his military reputation. He was the originator of first aid to the wounded in the field. He was the first to use the splint for fractures of the arm and leg. He was the first to use the tourniquet for hemorrhage. He was the first to use the amputation for the treatment of compound fractures. He was the first to use the antiseptic for the treatment of wounds. He was the first to use the anesthetic for the treatment of surgical operations. He was the first to use the electric current for the treatment of neuralgia. He was the first to use the galvanic current for the treatment of paralysis. He was the first to use the magnetic current for the treatment of rheumatism. He was the first to use the light for the treatment of ophthalmia. He was the first to use the heat for the treatment of scalds and burns. He was the first to use the cold for the treatment of hemorrhoids. He was the first to use the steam for the treatment of skin diseases. He was the first to use the vacuum for the treatment of ulcers. He was the first to use the pressure for the treatment of varicose veins. He was the first to use the traction for the treatment of dislocations. He was the first to use the extension for the treatment of fractures. He was the first to use the immobilization for the treatment of sprains. He was the first to use the rest for the treatment of all injuries.

Fig 4 Result of physical therapy combined with splinting of the hand in the position of function in a case of neglected infection involving the radial and ulnar bursæ
a, b, Appearance and position of hand at beginning of treatment c, Metal splint, similar in principle to that illustrated in Figure 3, with elastic band to abduct and rotate thumb d, Result at time wound discharge had ceased

ately adds to the patient's comfort and perhaps permits him the first relief from pain

If the inflammatory reaction associated with a spreading infection is added to the hemorrhage and tearing of tissue that result from injury, rest is even more important, and if it can be provided with the affected part in the position of function (Figs 3, 8), the ultimate result will be most satisfactory (Fig 4)

If contractures have developed as a result of neglected injuries or long continued infec-

tions, much can be accomplished by the use of splints which bring constant tension to bear upon scar tissue, whether it involves the superficial tissues, the muscles, the tendons, or the joint capsules The principle involved has long been accepted, and the use of tension in overcoming contractures, particularly of the von Volkmann type, advocated long ago by Claude Martin and his pupils in France and by Sir Robert Jones in England, has been the most important factor in the successful treat-

Fig 5 Glove fitted with buckles and straps to permit application of tension to fingers stiff in extension Tension can also be exerted upon the thumb if a buckle for the thumb strap is attached to the ulnar side of the glove at the level of the web

Fig 2 Padded aluminum splint to relax the abductors and extensors of the thumb and the extensors of fingers and wrist. It can be easily removed for cleansing of the hand and application of physical therapy and easily reapplied.

attempting to board a moving car, or he twists the fingers and thumb as he clutches at some support to keep himself from falling. The hand and wrist are painful and swollen, perhaps slightly discolored. Pressure over the ulnar side of the wrist joint or over the metacarpophalangeal joint of the thumb causes exquisite pain. Certain movements exaggerate the pain. X ray examination shows no evidence of chipped or of linear fractures. A sleeve of stockinet is drawn over the hand, and a plaster bandage is molded smoothly over volar surface of hand and forearm while the hand is held in the position of function—dorsiflexion

at the wrist, semiflexion of thumb and fingers, abduction of thumb from hand, palm facing the patient. The free ends of the stockinet are turned back to cover the upper and lower edges of the plaster splint. A muslin bandage is applied firmly and smoothly over the hardening plaster, and almost before the dressing is completed the patient expresses the relief he has obtained from the immobilization and the smooth pressure of the bandage.

Fig 3 Splint for maintaining the hand in the position of function.

Fig 8 Splint for supporting fingers in extension and thumb in extension and abduction after suture of extensor tendons or injury of radial nerve By bending the distal end of the splint slightly to permit semiflexion of the fingers this splint serves equally well for maintaining the hand in the position of function

ber of cases in which open wounds of the dorsum of the hand have been followed by infection and sloughing of covering tissue and extensor tendons. By splinting the hand in dorsal flexion at the wrist and almost complete extension at metacarpophalangeal and interphalangeal joints, and by treating the open wound with cleanly surgical care, and in some cases with a skin graft of intermediate thickness, healing has been obtained in such cases and a bridge of scar tissue formed between the ends of widely separated tendons, which acted as a substitute for the extensor tendons and permitted the fingers and hand to be brought to a straight line when healing was complete. Although the fingers could not be maintained in complete extension when the hand was held in hyperextension at the wrist, the functional results were satisfactory and the necessity for technically difficult operative procedures avoided.¹

If tendons have been sutured the part should be immobilized in such a position that mini-

mum tension is put upon the suture line. Otherwise one of several unfavorable results occurs: the suture material cuts through the tendon ends and fails to hold them in approximation, or the suture material gives way completely; or, at best, the fibroblastic and fibrous tissue which forms to unite the tendon ends is stretched to such a degree that the tendon is lengthened and the maximum contraction of the muscle belly is not sufficient to take up the slack.

If flexor tendons of thumb or fingers have been sutured relaxation is best obtained by flexion at wrist and metacarpophalangeal joints (Fig. 7). The fingers should not be sharply flexed at the interphalangeal joints. Flexing the fingers about a roller bandage in the palm after suture of their flexor tendons frequently results in fixation of the tendons within their digital sheaths and a contracture exceedingly difficult to overcome. After suture of extensor tendons relaxation of fingers or thumb can be obtained by dorsal flexion at the wrist and complete extension at metacarpophalangeal and proximal interphalangeal joints (Fig. 8).

3 NERVE INJURY

Sir Robert Jones in a lecture to a group of American medical officers once stated his be-

¹If there has been loss of both covering tissue and tendons on the dorsum of the hand and healing takes place by scar tissue formation, one can not hope to unite the separated tendons or to replace the destroyed tendons with grafts without first securing a covering of normal skin and subcutaneous tissue to replace the destroyed covering tissue. The attempt to make an incision in scar tissue, dissect it from its bed to expose injured tendons, and then replace it and suture the incision will end in extensive sloughing and loss of tissue because of the low vitality of the scar tissue covering.

Fig. 6 Complete restoration of function of thumb resulting from simple splinting of thumb in abduction and extension for 4 weeks following division of extensor pollicis longus

ment of this condition. Purposeful splinting in the treatment of contractures involves the use of splints which permit the application of steady tension for prolonged periods of time, which do not produce excessive pain, and which can be easily adjusted and easily applied and removed so as to permit active use of the hand and the application of physical therapy in conjunction with the use of the splint. In cases in which the small joints of the hand have become stiff in extension the use of a glove fitted with straps and buckles, which permit the fingers to be drawn into a flexed position (Fig. 5), often is helpful.

2 DIVISION OF MUSCLES AND TENDONS

The retraction toward its origin and to a lesser extent toward its insertion that takes place the moment a muscle belly or its tendon

Fig. 7 Dorsal splint for securing relaxation of flexor tendons of fingers. The maximum flexion should be at wrist and metacarpophalangeal joints

is divided, is a well recognized fact. Released from their normal tension muscle fibers immediately contract to a position of rest. If the muscle or tendon is completely divided, and if the tendon glides in an individual sheath, as does the flexor pollicis longus for example, no amount of restraint or fixation of the affected part will prevent separation of the two ends or permit satisfactory healing without approximation by surgical operation. If, however, the muscle or tendon is not completely divided, or if its retraction is checked by bands or fibers of attachment to adjacent tendons, such as unite adjacent extensor tendons on the dorsum of the metacarpus or if it is fixed to some extent by areolar tissue such as surrounds the extensor pollicis longus on the dorsum of the thumb, immobilization of the part in a position that brings the insertion of the muscle as close as possible to its origin offers a reasonable chance that operation may be avoided. Such immobilization should be carried out in every case in which immediate operative treatment is contra indicated because of the conditions under which the wound has been sustained or because the most favorable time for operative care has passed before the patient is seen by the surgeon. Four times in recent years we have seen restoration of function of the completely divided extensor pollicis longus follow immobilization of the thumb in the completely extended position with the help of a splint applied 24 hours after injury and kept in place for a period of four weeks (Fig. 6).

Satisfactory though not completely successful, results have been obtained in a num-

Fig 11 Splint for supporting fingers in semiflexion at metacarpophalangeal joints after suture of median and ulnar nerves. Strap shown in Figure 10 is attached to ulnar side of splint. Above, Appearance of hand 3 months after injury and repair of divided median and ulnar nerves and all flexor tendons. On attempting to straighten the fingers they fall into hyperextension at metacarpophalangeal joints because of lumbrical and interosseous paralysis. Below, Result 14 months after injury. Splint shown was worn constantly for 11 months to prevent overstretching of paralyzed muscles.

words, after suture of median and ulnar nerves just above the wrist the fingers must be supported in slight flexion at the metacarpophalangeal joints and the thumb in rotation and partial adduction during the period of from 9 to 15 months that is required for the slow downward growth of nerve axons. One patient recently under observation, a 12 year old boy operated upon a few hours after injury by Dr. Russell Bothe, then surgical resident at the Cook County Hospital, wore out the felt covering and leather straps on his splint three times during the course of a year, but the result obtained justified the trouble and inconvenience involved in the treatment (Fig. 11).

Fig 12 Pattern (in black) for making a simple splint to support hand in position of function. When at rest the longitudinal axis of the hand, *de*, makes a slight angle with the axis of the forearm, *ef*. The line of the metacarpophalangeal joints, *ba*, is not quite transverse to the long axis of the hand, and makes a still greater angle with the long axis of the forearm.

When the splint is cut along the line *a'c*, and the flat sheet distal to the line *ba* rolled into a small cylinder the splint lies smoothly on hand and forearm without pressure on thenar area. A few blows of the hammer are needed to gutter the part over the forearm and a slight bend in dorsal flexion at the wrist.

If the radial nerve is divided above the origin of its motor branches the paralyzed extensors and abductors must be supported in the relaxed position. Such a position involves abduction as well as extension of the thumb (Fig. 8). Simply to support the fingers and thumb on a flat splint dorsiflexed at the wrist is to ignore the importance of abduction in the function of the thumb.

THE PREPARATION OF SPLINTS

Since the surgeon may be called upon at any moment to provide a splint for any one of many indications and for any size of right or

Fig 9 Typical appearance of hand following division of median nerve and flexor pollicis longus the atrophy of thenar eminence and inability to rotate the thumb to oppose the fingers are characteristic of median nerve injury a b Before operation c d Degree of flexion at interphalangeal joint of thumb possible 3 weeks after operation

lief that if the hand and fingers were allowed to fall into complete flexion only once after a division of the radial nerve, an irreparable injury of the extensor muscles resulted. If a single overstretching of paralyzed muscle fibers causes irreparable injury, it is obvious how serious must be the effect of permitting paralyzed muscles to be continually overstretched by powerful and unopposed antagonists. The

typical deformity of the hand that results from the paralysis of the small muscles of the hand following injury or division of median and ulnar nerves is recognized by every medical student. Curiously enough though we take great pains to teach the student the meaning of the "ape hand," the flat and wasted thenar eminence (Fig 9), the hyperextension at metacarpophalangeal joints, rarely is it emphasized that with adhesive strapping or a leather wristlet with suitable attachment it is possible to rotate the thumb to face the fingers (Fig 10), or that with a simple and light splint the fingers can be supported in slight flexion at the metacarpophalangeal joints (Fig 11) and the thumb adducted toward the hand and so paralyzed thenar muscles, lumbrical and interosaeus muscles and adductors of the thumb can be protected from the harmful effects of continued overstretching.

If the maximum value of such treatment is to be obtained for the patient it must be persisted in until functional restoration takes place. Sir Robert Jones expressed it tersely, "The most skilful operation performed on the most suitable case will prove a fiasco unless the affected muscles are continually kept relaxed until recovery takes place." In other

Fig 10 Simple strap apparatus for rotating thumb so as to face fingers the strap attached to the loop around the thumb is buckled to the wrist strap on the dorsum of the wrist

has more elaborate tools and metal cutting instruments at his command.

A few standard patterns serve as a basis for the great majority of splints required in ordinary surgical practice

1 *Volar cock-up splint* This splint (Fig 3) is designed primarily to support the hand in the position of function, dorsiflexion at the wrist, semiflexion at metacarpophalangeal joints and thumb abducted from the hand. Support of the hand in such a position during the long period of convalescence from a severe infection or an extensive burn greatly simplifies the problem of restoration of function when healing is complete. If used in the presence of acute infection the splint can be sterilized and incorporated in a large warm wet dressing. At a later stage it can be padded with soft rubber which can be easily cleansed and autoclaved if necessary. If used when little or no wound discharge is present it can be covered with felt and provided with straps and buckles to facilitate application and removal.

In making a pattern for the splint the normal hand of the patient is laid palm downward on a sheet of white paper and a tracing made of the hand and forearm (Fig 12). Three points are marked on the tracing *a*, the radial border of the hand at the level of the second metacarpophalangeal joint; *b*, the ulnar bor-

Fig 16 A splint to produce extension of semiflexed fingers and wrist with the aid of elastic tension

der of the hand at the level of the fifth metacarpophalangeal joint, *c*, the radial border of the forearm at the level of the radial styloid. An outer line, *xyz*, is added to give a rectangular shape to the distal end of the pattern. A crescentic section is cut from the pattern along the line *a'c* so as to eliminate pressure upon the thenar eminence. The rectangular portion of the splint distal to the line *aab* is rolled into a cylinder of small diameter in such a way that the long axis of the cylinder lies exactly parallel with the line *ab*. The cylinder should rest easily between thumb and fingers and permit

Fig 15 Splint for application of elastic tension to semiflexed fingers and thumb lying alongside hand

Fig 13 The same splint as in Figure 3 with cross bar straps buckles springs and loops for the production of elastic tension on fingers and thumb (In a left above and c below only one strap buckle spring and loop are shown so as to make the illustration clearer)

left hand he must have available adaptable material and means of fashioning it to the required end

For simple immobilization for a relatively brief period of an injured hand or forearm without an open wound nothing is more satisfactory than plaster of paris smoothly molded over closely fitting stockinet on dorsal or volar surface of the injured extremity Thumb or fingers can be included if necessary, or the splint stop short at any desired level to permit movement at certain joints

For most other purposes—for patients with open wounds, for tension splints, for splints requiring frequent removal and particularly for splints intended for use for long periods of time—aluminum has been found particularly useful and adaptable Sheet aluminum .064 inches in thickness, designated by the manufacturers No 2 S $\frac{1}{2}$ H, can be easily cut to the desired size with ordinary "tin snips" It is sufficiently rigid to maintain any desired shape, and still light enough not to be cumbersome With a few simple tools which can be kept in a drawer in the splint room—snips a hammer, a jig saw to cut finger pieces, bending irons, file and sandpaper to smooth rough edges, a small drill to bore holes, rivets with which to attach a thumb piece—and with a vise in which the splint can be firmly held as it is fashioned and smoothed off, splints for most purposes can be promptly and easily prepared For hinged splints and tension splints with slotted finger pieces we depend upon the splint maker who

Fig 14 A splint designed to produce the same effect as that in Figure 13 but to be applied to the dorsum of the hand

has more elaborate tools and metal cutting instruments at his command.

A few standard patterns serve as a basis for the great majority of splints required in ordinary surgical practice

I. Volar cock-up splint This splint (Fig 3) is designed primarily to support the hand in the position of function. dorsiflexion at the wrist, semiflexion at metacarpophalangeal joints and thumb abducted from the hand. Support of the hand in such a position during the long period of convalescence from a severe infection or an extensive burn greatly simplifies the problem of restoration of function when healing is complete. If used in the presence of acute infection the splint can be sterilized and incorporated in a large warm wet dressing. At a later stage it can be padded with soft rubber which can be easily cleansed and autoclaved if necessary. If used when little or no wound discharge is present it can be covered with felt and provided with straps and buckles to facilitate application and removal.

In making a pattern for the splint the normal hand of the patient is laid palm downward on a sheet of white paper and a tracing made of the hand and forearm (Fig 12) Three points are marked on the tracing. *a*, the radial border of the hand at the level of the second metacarpophalangeal joint, *b*, the ulnar bor-

der of the hand at the level of the fifth metacarpophalangeal joint, *c*, the radial border of the forearm at the level of the radial styloid. An outer line, *xyz*, is added to give a rectangular shape to the distal end of the pattern. A crescentic section is cut from the pattern along the line *a'c* so as to eliminate pressure upon the thenar eminence. The rectangular portion of the splint distal to the line *aab* is rolled into a cylinder of small diameter in such a way that the long axis of the cylinder lies exactly parallel with the line *ab*. The cylinder should rest easily between thumb and fingers and permit

Fig 15 Splint for application of elastic tension to semiflexed fingers and thumb lying alongside hand

Fig 17 Splint for applying tension to flexed fingers and drawing pronated hand and forearm into position of supination in a case of Volkmann's contracture. The hand and forearm are drawn into supination by strap across wrist and tension upon thumb traction of splint to lower half of arm holds it in position

flexion of the fingers at the metacarpophalangeal joints. Its long axis lies almost transverse to the vertical axis of the hand piece, *de*, and the latter forms a slight angle with the vertical axis of the forearm piece, *ef*. When the splint is guttered so as to lie smoothly on the forearm, and bent slightly at the wrist joint so as to provide dorsal flexion at the wrist joint, it should support the hand comfortably in the position of function (Fig 3, d).

2 Splint for extension of fingers and thumb
If it is desired to hold the fingers and thumb in extension, for example, after suture of extensor tendon or injury of radial nerve, the splint is prepared from a pattern similarly made but the added portion, *xyz*, is omitted, and a thumb piece is added by riveting to the splint at the proper angle a single strip of aluminum, 1 inch wide and turned in such a way that the thumb rests easily upon it (Fig 8).

3 Splint to apply tension upon fingers at metacarpophalangeal or interphalangeal joints
If it is desired to put tension upon stiff metacarpophalangeal or interphalangeal joints while the hand is held in dorsal flexion at the wrist joint a bridge or arch of aluminum can be riveted to the splint (Fig 13) and from it tension

applied to each digit. A loop to slip over each finger, and united to a corresponding loop on the bridge with a tension spring, a buckle and strap constitute a device easy to apply and remove, and easy to adjust to any degree of tension.

4 Dorsal splint for application of tension upon fingers
If because of volar scars or open wounds it is found undesirable to place the splint on the volar surface of the forearm a similar effect can be obtained by making the splint in two pieces, one for forearm and one for hand, and uniting them with a hinge at the wrist joint. Dorsal flexion of the desired degree can be obtained by a stout spring strap and buckle running from the distal end of the hand piece to the forearm piece (Figs 14, 15). The pull on individual digits can be obtained by adding a bridge or arch, and straps and springs for individual digits just as with the volar cock up splint.

5 Splint for application of tension on flexed fingers
The hinged dorsal splint can be used to advantage in cases of flexion contracture of the fingers whether the contracture is of the typical Volkmann type or whether it has followed infection or injury other than the type

cal injury about the elbow joint which leads to Volkmann's contracture. If the contracture is not too marked and the fingers can be partially extended a splint such as that illustrated in Figure 17 is useful. The thumb piece permits the application of tension to the thumb, the direction of the line of tension can be changed as desired, usually the thumb needs to be abducted from the hand so as to increase the span between thumb and index finger.

If the fingers are sharply flexed into the palm a splint which permits a pull directly distalward instead of dorsalward is required. Such a pull can be obtained with loops, springs and buckles attached to elongated finger pieces (Fig. 17) or by lengthening the slotted finger pieces shown in Figures 16 and 17 and bending them at a right angle near their distal ends.

Since this type of splint is usually required for advanced cases of Volkmann's contracture two other features are usually added to it. a thumb piece, extending outward from the splint opposite the base of the thumb, and a short arm piece, attached to the forearm piece by a hinge at the elbow, which serves both to keep the splint from being displaced distalward along the forearm, and so neutralizing the tension, and as a fulcrum from which tension in the direction of outward rotation of the forearm can be obtained (Fig. 17).

The latter is important in those cases in which the hand with sharply flexed fingers is constantly held in pronation. Unless it can be drawn into supination at the same time that the fingers are drawn into extension the result

Fig. 18 Modification of Lewin's baseball finger splint for supporting a single finger in extension after suture of extensor tendons

will not be satisfactory. With the splint held in a fixed position with the aid of the arm piece the hand and forearm are drawn toward the position of supination with the help of a broad strap across the wrist joint and the outward pull upon the semiflexed thumb.

Other modifications of these splints will suggest themselves to anyone who is constantly confronted with the treatment of injuries of the hand. A single extension piece, for example, can be added to the volar cock-up splint and permit application of tension to a single digit while the others are supported in the position of function. For a fracture of a proxi-

Fig. 19 Splint for applying tension upon a proximal interphalangeal joint left immobile in flexion after division of the extensor tendon. The proximal phalanx is drawn toward the splint by a circle of garter elastic.

mal phalanx, of a metacarpal, or for a Bennett's fracture of the metacarpal of the thumb such a splint is helpful. To support the fingers in abduction after separation of fused fingers and the application of a free graft a flat splint can be prepared with individual finger pieces widely separated. Such a splint gives support and immobilization and at the same time permits the application of sponge pressure over the grafts between the separated fingers. To support a single finger in complete extension a modification of Lewin's baseball finger splint is useful (Fig 18). To bring elastic tension to bear upon an interphalangeal joint after the finger has been left immobile in flexion following division of the extensor tendon a modification of Bunnell's safety pin splint (Fig 19) can be used to advantage.

It is hardly necessary to add that much effort and ingenuity have been expended by many men to devise satisfactory splints for immobilizing and protecting the injured hand. The cockup splint of Sir Robert Jones for supporting the hand in dorsiflexion at the wrist is known to every surgeon. The "baseball finger" splint of Lewin and the "safety pin" splint of Bunnell for producing extension at the proximal interphalangeal joint have been mentioned. William E. Browne's ingenious and adaptable splint can be utilized for many of the conditions referred to in the preceding pages.

SUMMARY

Purposeful splinting following injuries and infections of the hand involves at least three important principles: (1) securing rest for injured and inflamed tissues, whether soft tissues, tendons, muscles, joint capsules or bones, (2) securing relaxation of muscles whose ten-

dons have been divided or whose nerve supply has been injured, (3) bringing constant and prolonged tension to bear upon scar tissue whose gradual contraction interferes with the function of the hand. The studied application of these principles can aid very definitely in bringing about restoration of function after injury and infection have taken place.

FLUID BALANCE IN THE PUERPERIUM

E GRANVILLE CRABTREE, M D , F A C S , Boston, Massachusetts

THE more we add details to the sum of knowledge about any common disease when it occurs in patients who are in, or immediately past, the period of gestation, the more it appears that pregnancy distorts the picture from that presented in the non-pregnant. This conviction and noted instances of undoubted polyuria after delivery have supplied for me the impetus to investigate fluid balance in the puerperium as a distinct entity. I am conscious of the fact that the methods employed in obtaining these data fall far short of scientific requirements in completeness, a complete study is more fittingly performed in a well equipped laboratory and then on comparatively few patients. It may not be wasted effort if, from a more gross demonstration of the essential findings in a larger group of cases, intensive study of a smaller group may be stimulated and carried out under proper laboratory conditions.

In the beginning I wish to present a group of hitherto unassociated observations which indicate first, that the pregnant woman fails to eliminate fluids as adequately as does the non-pregnant woman, and second, that the storage of fluids in the blood stream and tissues of the body in the course of a normal pregnancy may, and probably does, without production of anasarca, take place elsewhere in the body besides in the obvious place for fluid increase, that is, in the products of pregnancy.

These observations fall under three headings

- 1 Evidence of increased fluid content of the blood
- 2 Evidence of retardation in the mechanism of conducting secreted urine away from the secreting unit, the renal cortex
- 3 Functional tests, in so far as they have yet been applied to pregnant women, paradoxically indicate decreased functional activ-

ity without evidence of storage of waste products of metabolism in the blood stream

Whatever may be the etiology of the storage of fluids in pregnancy, if it exists, the wisdom of such provision is obvious. At delivery, there occurs a sudden and excessive drain upon body fluids which is immediately followed by further encroachments during the immediate postpartum period. Within a very short time, the patient eliminates from her body the products of her pregnancy, accompanied by the loss of blood and excessive radiated fluids attendant upon her exertions. The fluid losses at delivery may be enumerated as amniotic fluid, fluid content of the baby, blood and fluid content of the placenta, blood loss of the mother, and excessive lung and skin radiation. The ensuing postdelivery losses within the 14 day convalescence covered in this study are lochia, some of which is included inadvertently in the urine and the remainder caught in pads, and mammary gland secretions. Loss of fluid through these two factors, while not measured or allowed to enter into this problem, are considerable. The "milk department" of the Boston Lying-In Hospital states that during the first postpartum days, average secretion from the mammary glands is 15 ounces but that it soon rises to 32 to 40 ounces with peak output for individual patients as high as 64 ounces each 24 hour period.

In the studies here recorded, no consideration is given to the fluid loss at delivery or to the lochial and milk loss during the puerperium. The record comprises only the liquid food and water intake to determine the intake curve, and the urinary excretion with whatever lochia may accidentally be included, to determine the output curve. The period covered begins immediately upon delivery but does not include urine removed by catheter during delivery and continues to the end of 14 days, at which time patients are normally discharged from the hospital. Wherever unavoidable loss of urine has been encountered,

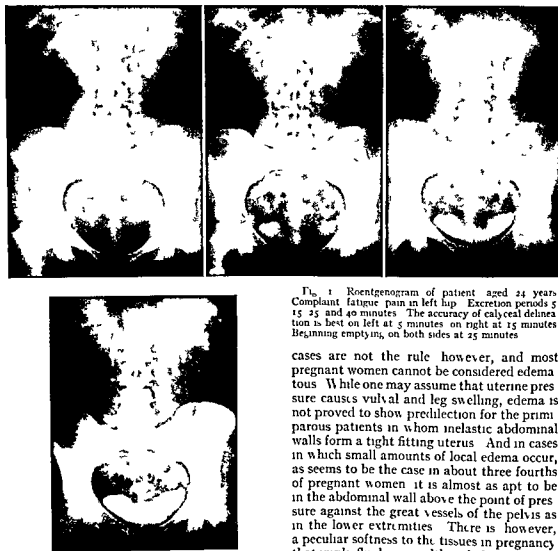

FIG. 1. Roentgenogram of patient aged 34 years. Complaint fatigue pain in left hip. Excretion periods 5, 15, 25 and 40 minutes. The accuracy of calyceal delineation is best on left at 5 minutes, on right at 15 minutes. Beginning emptying, on both sides at 25 minutes.

the graphs are so marked. Credit should here be given to the nurses of the Boston Lying In Hospital, who, under the direction of Miss Garran, showed both painstaking attention to detail and ingenuity in obtaining accurate records.

One may more readily accept the obvious premise that there is abundant need for excess fluid in the body of a woman who is about to undergo delivery than prove its presence. A few women because of extensive edema can safely be assumed to have excess fluid. These

cases are not the rule, however, and most pregnant women cannot be considered edematous. While one may assume that uterine pressure causes vulval and leg swelling, edema is not proved to show predilection for the primiparous patients in whom inelastic abdominal walls form a tight fitting uterus. And in cases in which small amounts of local edema occur, as seems to be the case in about three fourths of pregnant women, it is almost as apt to be in the abdominal wall above the point of pressure against the great vessels of the pelvis as in the lower extremities. There is however, a peculiar softness to the tissues in pregnancy that imply fluid excess although demonstrable edema may be entirely absent. In the Boston Lying In Hospital an energetic cardiac clinic promptly labels circulatory deficiencies. In the patients studied the cardiac cases are noted and their classification given.

During the period covered in this study no attempt was made to segregate types of cases. It seemed wiser that all types should be included irrespective of their clinical complications in order that a cross section of obstetrical cases might be obtained. The result was that the whole hospital population was put on

Fig 2 Roentgenogram of primipara, unit history No 23,052. Complaint transitory albuminuria. Study case, 2½ months pregnant, uninfected. Excretion periods 5, 15, and 30 minutes. Best plate 15 minutes.

measure and record charts. For this reason there are only small numbers of each of the groups except the normal deliveries. In most instances the number in each subdivision is too small to justify deductions from them except in comparison with the whole group.

In this communication the probability of excess fluid in pregnant women is established by deduction from present known facts concerning pregnancy. The study demonstrates that in 55 cases, with the exception of 5 in which, owing to rapid increase of fluid intake because of infection, output lagged behind intake beyond the 14 day period, there was but one instance in which there was not a readjustment of fluid balance during the puerperium in which the output of urine exceeded the intake of fluid by a total of from 3 ounces to 214 ounces extending over a period of from 1 to 8 days. I shall therefore assume that this phenomenon implies an excess of body fluids which may be capable of withstanding the fluid losses of delivery, lochial loss during the postpartum, and lactation during the 14 day study period, and still show the need for readjustment, if the normal situation of intake exceeding output by the amount of the normal body fluid losses through respiration, skin

radiation, fecal fluid content, etc., is to be reapproached.

In estimation of the etiology of fluid storage in pregnant women, one turns immediately to the well known renal dilatations of pregnancy which are now recognized as being almost universally present. They undoubtedly vary both in time of appearance and in extent. This may be so because of variable mechanical pressure factors in which the uterus obstructs the ureters to varying degrees. Pressure alone now seems inadequate to explain pelvic and ureteral changes in pregnancy. The modified endocrine state in pregnancy must be added to pressure to explain the renal changes in the gravid state. The degree of endocrine variation may not be any more constant than pressure mechanics either in one individual at various periods or among individuals. I know of no data from which I can assume that the effect of the pregnancy hormonal state is to produce impaired secretive action in the renal substance. In fact, intravenous urography indicates prompt secretion of the media into the calyces. I believe that until more data are collected from studies of endocrine effect on organs, we are justified in assuming that muscular atony of

Fig. 3. Roentgenogram of primipara, unit history No. 18192. Complaint: acidosis and vomiting. Pyelography at 6 months, uninfected. Excretion periods: 5, 15, and 45 minutes. Best plate: 45 minutes. Dye appears in calyces of both kidneys at 5 minutes. Dense concentration of dye in calyx on right and in calyx, pelvis, and ureter on left at 15 minutes. At 45 minutes, right ureter only dimly outlined; left ureter excellently outlined.

the conduction apparatus is the factor concerned. Failure to remove secreted fluids from the secreting unit may impair fluid clearance from the kidneys, as prostatic obstruction of the bladder seems to be followed by polyuria when constant drainage is established.

I am prepared to accept a double etiology for these renal changes which take place in pregnant women. They seem to me to be capable of playing the major rôle among significant factors favoring storage of fluids during pregnancy. They are first relaxation of the musculature of calyces, pelvis, and ureters as a manifestation of a changed endocrine state in pregnant women, and second pressure of the abdominal wall as well as gravity, which tends to force the inverted cone-shaped uterus into the inelastic bony pelvis, across the brim of which the ureters pass in an exposed position, the right one more so than the left. It is not now possible to dissociate these two factors in importance in estimating roentgenographic appearances and physiological behavior of the changed renal tree. The evidence now available seems to indicate that endocrine changes are at least of equal im-

portance with pressure in producing this phenomenon. Both in pregnant women and in pregnant quadrupeds, when the pressure factor can be almost if not completely eliminated, evidence has been produced in the several investigations which I shall mention to indicate that atonic relaxation of the renal tree begins almost immediately in pregnancy, and that it antedates the presence of sufficient uterine enlargement to produce pressure against the ureters.

I do not doubt that pressure accentuates pelvic and ureteral changes in women over quadrupeds. It also is the only acceptable explanation to date of unequal degree modification of the right renal tree over the left in pregnant women. Renal changes seem to begin quite early in the latter and to become progressive in degree throughout the greater part of pregnancy. Pressure changes appear to be mechanically possible only from shortly before mid pregnancy on to term, yet in most of the several researches noted there appears to be partial relief from renal embarrassment in the latter weeks of pregnancy without improvement in the mechanical set up which

Fig 4. Roentgenogram of primipara, unit history No 23,234 Pyelography at 6 months Complaint right renal distress Excretion periods 5, 15, and 40 minutes Only calyces fill at 5 minutes At 15 minutes right calyx dense, left pelvis and ureter dimly outlined At 40 minutes, right ureter not yet filled, left pelvis and ureter clearly outlined

makes pressure against the ureters possible Those changes in the behavior of the renal tree in regard to secretion and clearance of urine, which antedate a mechanical set up that can conceivably bring pressure to bear against the ureters, must be attributed to some other factor

Rowntree, in a summation of known facts regarding water balance (1922), states that the endocrine system unquestionably plays a part in the control of this balance and that polyuria follows extirpation of the posterior lobe of the pituitary body Further work in succeeding years has indicated a fluid balance disturbance during the catamenia and that the pituitary body participates in the changed endocrine state of pregnancy and the puerperium

I have assembled 7 observations, most of them from dissociated sources, all of which seem to me to be trustworthy In these there is a striking uniformity in findings The changes which are discussed appear uniformly to assert themselves in the first trimester of pregnancy, reach a peak of effectiveness in mid-pregnancy, and most of them show an upward trend beginning about the

eighth month of pregnancy These observations collectively, as well as each in its own right, seem to indicate the probability that fluids are stored in the body of the pregnant woman in the course of her 9 months' gestation

The first of these citations has to do with dilution anemia (Minot, Straus, Castle, Rowland, Wills, Talpade, 2) Briefly stated, the normal blood picture of the non-pregnant changes during the first 4 months from a hemoglobin reading of 80 to 85+ per cent and a red cell count of 4,000,000 to 4,500,000, to a hemoglobin reading of 60 to 70 per cent and a red cell count of 3,000,000 to 3,500,000, with definite evidence of improvement in both hemoglobin and cell count beginning at the eighth month of gestation This variation is due entirely to increase in plasma The cells are normal in number and character The condition is not improved by liver, iron, or other therapeutic measures In other words, there is a normal cell constitution but an excess of the fluid content of the blood

The second item of evidence is provided by animal experimentation Rossi has recorded his observations on the effect of preg-

Fig 5 Same case as Figure 4. Two months postpartum. Excretion periods 5, 15 and 30 minutes. Best delineation of pelvis, calyces and ureters at 5 minutes.

nancy in rabbits on the time after injection of intravenous pyelography media at which x ray evidence of the greatest concentration of dye is obtained. In non pregnant dehydrated rabbits, the best plates are obtained in from 3 to 5 minutes after injection of the media. In rabbits in the twentieth to twenty fifth day of pregnancy, the best plates are obtained from 15 to 20 minutes after injection. Abramson, Robins, and I are now engaged in repeating this experiment, and we believe Rossi to be correct. These observations might be interpreted to indicate that there is reluctance on the part of the kidneys of the pregnant rabbit to give up the dye as promptly as in the non pregnant. This might be construed as indicative of deficiency in the renal cortex were it not that the calyces of the kidneys appear to fill as readily in pregnant as in non pregnant animals. The defects in the earlier plates in pregnancy seem to be due to failure of the media to become distributed throughout the pelvis and ureter.

The third item of evidence is that which my collaborators and I have produced and which concerns a similar delay in appearance of the 'best film' in the pregnant human as compared with the normal woman of similar

age group. It is generally agreed among radiologists and urologists that in non pregnant normal individuals the best roentgenographic demonstrations are obtained soon after injection of the intravenous media. The 5 minute plate is most often the best, the 10 minute plate next in frequency, and rarely the 15 minute plate shows to best advantage (Fig 1). In a survey of 253 pyelographies in pregnant women (1) the best plate in mid pregnancy is most often obtained at 30 minutes after injection of the media. As early as 2½ months in pregnancy (Fig 2) the 5 minute and 10 minute plates are oftener inferior to the 15 minute plates.

In a more advanced pregnancy (fifth to eighth month) there is a tendency to fill the calyces early, but there is noted a definite lag in distribution of the dye throughout the pelvis and ureter (Fig 3). In the more marked stages of dilatation of the pelvis and ureter adequate delineation of the pelvic and ureteral outlines is not obtained until after 45 minutes (Fig 4). But soon after the termination of pregnancy, the kidneys return to their normal excretion rate (Fig 5). In extensively changed large lesions adequate outlining of the pelvis and ureter are not obtained until

Fig 6 Roentgenogram of tripara, unit history No 4,343 Pyelogram made at 6 months Complaint bilateral pyelitis of pregnancy Excretion intervals 5, 15, and 45 minutes Abnormal kidney right, greater dilatation on left Calyces fill both sides at 5 minutes Ureters first show both sides at 45 minutes

from 45 to 90 minutes (Fig. 6) In infected cases, the calyces may not fill at all

The fourth item of evidence is drawn from the study of the ability of pregnant women to eliminate a peak load of fluid This evidence is produced by Janney and Walker The conditions of their experiment were aimed at the determination of what percentage of an enormous intake of water would be excreted in a 30 minute period in normal women as controls and in women in the different weeks of pregnancy They concluded that for normal women, intake and output volumes were identical In pregnant women, there is a marked and progressive decrease in the ability of the kidneys to handle peak loads of fluid, which reached its lowest figure in mid-pregnancy but which showed a slight upward trend in the latter portion of pregnancy

The fifth item is supplied by studies of motility of the pelvis and ureter by the hydrophoragraph Traut, McLane, and Kuder produced evidence to indicate that beginning early in pregnancy, there is a progressive decrease in motility of the pelvis and ureter which reaches its lowest level in mid-pregnancy and shows an upward trend at the eighth month

The sixth item of evidence produced is that of the clinical and experimental data concerning the curve of degree of dilatation noted in the months of pregnancy Traut, McLane, and Kuder record in a reversed curve the degree of dilatation of pelvis and ureters in contrast to the curve of motility of the musculature This curve has its peak in mid-pregnancy and declines steadily toward the end of pregnancy

The pyelography available for study at the Boston Lying-In Hospital, where ever repeated pyelography has been done, confirms this point of view From purely clinical observations both incidence of pyelitis symptoms and severity of symptoms and signs occur in mid-pregnancy It is only in the occasional case that pyelitis symptoms begin after the eighth month or are severe if they do occur

The seventh item in support of a changed renal behavior is that supplied by laboratory data Excretion of dyes from the kidneys as indicated by phthalein excretion or similar drugs is below normal Sondern and Harvey first showed (1911-1912) by intramuscular injection of phenolsulfonphthalein in 18 nor-

mal women late in pregnancy that there was in all a delayed appearance time for the dye from 8 minutes in the non-pregnant to 12 minutes in the pregnant women, and a total output in 2 hours of 45 per cent instead of 75 per cent average for 18 normal non-pregnant women. There were 3 cases among the 18 in which dye excretion was greatly depressed. Yet over a period of several years' observation, non-protein nitrogen tests are noted in the Boston Lying-In Hospital to range in the low normals, as do creatinines and other tests devised to indicate storage of waste products of metabolism. It seems logical to look upon this episode in dye behavior as similar to the excretion of intravenous pyelography media. In the latter, visualization of the pyelography media gives the clue to the failure of the dye to appear in the bladder promptly or in normal quantities. If the phenolsulfonphthalein and the dye are promptly excreted through the whole glomerular and tubular units, although delayed in reaching the outer world, there is no reason why there should be retention of waste products in the blood. It has not been demonstrated that there is appreciable re-absorption of fluids or urine salts from the mucous membrane lined conducting channels of the urinary tract. Only their removal from the body after passing through the secreting unit is delayed.

Analysis of these data indicates that there is evidence of increase in blood plasma in pregnancy. Edema stands as a further manifesta-

tion of excess body fluid during pregnancy in a few

There is a decreased ability to handle peak loads of fluids in pregnancy in normal women.

Pregnancy itself in animals (quadrupeds) and pregnancy alone but accentuated by uterine pressure does not appear to impair the excreting ability of the kidney, but impairs, through delay, the clearing of excreted urine from the renal tree.

It is therefore logical to expect storage of fluids during pregnancy and a re-adjustment in fluid balance soon after delivery.

In support of this hypothesis I have noted clinically isolated cases which indicated that there was excess excretion over intake immediately following delivery. In some instances an immense residue was found in the bladder so near to delivery, at which time the bladder had been emptied by catheter, that it seemed impossible that a sleeping patient could have taken that amount of fluid in that period of time. In one specific case, a total fluid intake of 3,765 cubic centimeters had been accompanied by an output of urine of 4,920 cubic centimeters, yet catheter revealed 1,890 cubic centimeters bladder residue in addition.

The duration of this experiment to determine fluid balance in the puerperium was terminated spontaneously by the limit of the ability of the nursing staff of the hospital to carry so accurate a recording of intake and output further. It resulted in the assembling of complete charts on 55 cases. By reference

Fig 7 Charts of 3 typical cases showing fluid balance of patients which emerge from delivery on fluids ad lib M A secundipara, upper respiratory infection, afebrile S B, secundipara, afebrile E E, primipara, afebrile
—intake, - - - - - output

but that the third, fourth, fifth, and sixth days show greater frequency of excess and greater amounts of excess

Total excretion of fluid in excess of intake was but 13 times under 30 ounces. Nine times it exceeded 100 ounces, and twice exceeded 200 ounces.

Reference to Table I reveals that it makes little difference in the number of days of excess secretion as to whether the patients emerge from delivery on ad lib fluids or on forced fluids. The figures are 4.0 days for the former and 4.3 days for the latter. There is, however, a larger amount of fluid handled. The average total excess excretion for the ad lib group is 68.3 ounces and for the forced fluid group 114.8 ounces.

In 2 other groups there might be factors outside those prevalent in normal pregnancy which might influence the relation of intake and output curves. Both groups are small, they are the pre-eclamptics and the cardinals, 5 of the former and 3 of the latter. The endocrine state is definitely variant from that in

normal pregnancy in the eclamptics. In spite of this variation the total excess fluid exceeded 83 ounces in 3 of the 5, and exceeded 100 ounces in 2 of the 5.

The cardinals might be considered as more likely to store fluids because of impaired circulation. They were also kept on greatly restricted intake of fluid. In spite of the latter, they were above the average in total fluids excreted, and excreted an excess for a greater number of days with an average for the 3 cases of 5.3 days.

I question whether it is possible so to restrict fluids in afebrile conditions in pregnancy that there is not produced a fluid storage in the course of the pregnancy, which is adequate to meet the fluid losses attendant upon delivery and the establishment of lactation in the puerperium if fluids are not curtailed up to the limits of deprivation.

A better graphic image of the nature of the disturbed fluid balance in the puerperium can be obtained by reference to the individual charts which are appended (Figs 7, 8, 9).

TABLE II—DISTRIBUTION OF DAYS OF EXCESS FLUID AFTER DELIVERY

	1	2	3	4	5	6	7	8	9	10	11	12	13	Home
Ad lib fluids	2	3	4	9	10	4	5	7	6	7	1	0	0	
Forced fluids	0	10	9	11	9	8	9	10	2	3	0	1	1	
Pre-eclamptics	0	3	3	3	2	4	1	0	1	1	0	0	0	
Cardiacs	0	1	2	2	3	2	2		1	1	0	0	0	
Total of all cases	3	10	11	29	25	3	17	22	11	6	2	1		

	Days of excess fluid	Average excess fluid (14 days)
Ad lib fluids	40	68.3
Forced fluids	43	114.8
Pre-eclamptics	36	81.8
Cardiacs	53	83.3
Total of all cases	132	77.4

to Table I it will be noted that the cases studied consisted of

13 cases of normal delivery in normal uninfected women who had taken fluids as desired without any effort at forced fluids. Fluid range per 24 hour period was 70 to 100 ounces

19 cases which emerged from delivery on forced fluids with a range of intake above 100 ounces

5 pre eclamptic cases, some of which had been dehydrated, others were taking fluids ad lib

4 infection cases with onset of infection soon after delivery. Fluids were gradually and steadily forced until the intake rose to 150 ounces or above

2 urinary tract infection cases which were on forced fluids similar to group No. 4

3 gonococcus endocervicitis cases in which fluids were ad lib

2 cases of retention of urine which were treated for but a few days by catheterization. Fluids ad lib

3 cardiac cases in which restricted fluids with intake between 40 and 70 ounces per day had been the routine

3 cases in which postpartum hemorrhage had occurred. Forced fluid was instituted and transfusion employed

In 1 case the data were insufficient for determining the fluid relation

In the whole group there were but 6 instances in which, for a period of from 1 to 5 days, there was not some time during which the intake of fluid was not exceeded by the output of urine. This phenomenon occurred even though the record of all other fluid losses attendant upon delivery and lactation were not included. This observation would in itself establish as a fact the presence of a definite fluid readjustment which regularly fol-

lows pregnancy and delivery. The figure is further strengthened by the necessary exclusion of 5 of the 6 cases in which the curves did not cross because of fever and forced fluids. It is well established that in febrile cases output of fluid through the urinary channels is markedly depressed. If in addition fluids are rapidly increased, the intake curve far outstrips the output curve. Yet in spite of such rapid increase in intake in febrile cases, the output curve appears to bear an abnormal relation to the intake curve in that it frequently approaches very near to crossing it in a relation which is not encountered in similar febrile conditions in the non pregnant. The relation of output to intake in these febrile cases was not studied beyond the 14 day period previously designated, there may have been a delayed readjustment.

In the chart of the remaining one normal individual whose output did not at any time exceed her intake, there is noted the same tendency for the output to approach abnormally near the intake on certain days.

It is evident that if among the many losses of fluid attendant upon delivery and the puerperium lactation alone was included in fluid loss in addition to urinary output the figures would appear abnormal to even a more astonishing degree.

Analysis of Table I and reference to Table II show that fluid excess is occasionally noted during the first 24 hour period after delivery is very commonly present on the second day

I shall not attempt to indicate the possible significance of fluid storage in pregnancy in relation to medical practices on pregnant women. Those who are better qualified in the various fields of medicine can best do that. That it has bearing on urinary infection in pregnancy, the treatment of cardiac cases in pregnancy, the management of eclamptics, and the demonstration of less need for attempting to maintain fluid reserves in postpartum conditions, is obvious.

I cannot refrain from observing that residual urines and retentions of large size may quickly occur wherever the response of the bladder to normal sensations is reduced as a result of bladder injuries caused by delivery or narcosis anesthetics. The relation of output to intake is no longer to be considered a safe guide as to the magnitude of the bladder content. Large bladder content if uninfected is of less significance than when infected. If infected, a postpartum febrile condition can be expected to occur with either retention or large residual urine formation. Theoretically, postpartum pyelitis can be considered entirely the result of faulty bladder management. It should be preventable. This increment of knowledge confirms me in my long established routine of placing on constant drainage those infected bladders and after 3 days of intermittent catheterization most uninfected bladders as soon as the fact of faulty emptying is established. I do not believe that the average nurse or obstetrician can palpate or percuss residual urine unless of large amount. Early catheterization of sleeping patients to prevent gross overdistention and subsequent atony is justified. Catheterization by the clock as is frequently practised is inconsistent with the demonstrated fluid excretion characteristics in the puerperium.

CONCLUSIONS

1 Pressure of the gravid uterus upon the ureters is not adequate to explain the changes

in the renal tree which commonly occur in pregnancy

2 A double etiology for these changes, if considered both as to nature and degree, should be accepted for humans. An endocrine factor should be given equal if not greater significance than the pressure factor.

3 There are several established lines of evidence which have in common certain characteristics in relation to the stage of pregnancy, which indicate that fluid storage in the course of pregnancy should occur regularly and in all cases.

4 In all except 1 of 54 cases studied over the average 14-day stay in the hospital after delivery, except in 5 febrile cases, there is an output of urine in excess of fluid intake too large and of too long duration to be considered accidental.

5 If fluid losses attendant upon delivery and the puerperium, purely obstetrical in nature, and lactation, be included, the above figures will be greatly exaggerated.

6 Medical and surgical and urological diseases, when they develop either in the course of pregnancy or the puerperium, should be considered in relation to a disturbed fluid balance and not by the yard stick of fluid balance in the non-pregnant.

struates beyond the age of 48 years, should be closely followed and the possibility of endometrial malignancy kept in mind

Associated hyperplasia Hyperplasia of the endometrium is a frequent finding in women with a late menopause, and may be a predisposing factor in the development of malignant changes. In 17 of our cases the histological sections showed an associated hyperplasia. One of these had been diagnosed as a case of endometrial hyperplasia from a curettage performed 12 months previous to the finding of positive evidence of malignancy.

Incidence of myomas While 35.2 per cent of our fundus cancer cases had associated myomas, only 5.6 per cent of the total number of patients with fibromyoma treated within the same period had associated carcinoma. This still leaves unanswered the question of the etiological relationship between uterine fibromyomas and fundus cancer.

Associated pathology—metastases Howard Taylor finds that breast carcinoma is associated with fundus carcinoma in the proportion of 1 to every 130 cases of the latter. In this small series, the incidence was somewhat higher, since there were 5 patients who had been previously treated for adenocarcinoma of the breast. One of these died 3 months following treatment, and at autopsy, in addition to the uterine adenocarcinoma, fibrosarcoma of the uterus, lung, and liver was present. The ovary was found to be involved in 4 cases. One of these showed a fibrosarcoma, while in another a granulosa cell tumor was found. This latter case invites speculation upon the relationship between excess ovarian hormone and the pathological changes occurring in the endometrium.

Classification of cases The comparison of results of different methods of treatment is of little value unless it deals with a uniform type of material. The rate of cure will necessarily vary with the care with which the primary material is selected and the principles which form the basis for selection. The importance of separating the operable cases when reporting results, has been stressed by Heyman (9) and Arneson, particularly when an attempt is being made to evaluate surgery and irradiation.

The clinical classification is further complicated by the fact that there exists a group of cases in which cancer can be demonstrated anatomically and histologically, in both corpus and endocervix. Heyman (10), who first drew attention to this, states that the possibility of comparing different statistics on corpus carcinoma will be entirely ruined if one clinic places these with the corpus cancers and another clinic groups them under the cervical cancers. He applies the term *carcinoma corporis et colli* to this type of lesion and classifies them separately under this heading. In the

CARCINOMA OF THE BODY OF THE UTERUS

A Clinical and Pathological Review

K. C. MORRIS, M. D. and PAUL I. MAX, M. D. St. Louis, Missouri

THIS study was undertaken with the object of reviewing and evaluating results in the treatment of carcinoma of the corpus uteri at The Barnard Free Skin and Cancer Hospital. It covers the years 1919 to 1936 within which period approximately 100 patients with corpus carcinoma presented themselves for treatment. The case records from the earlier years in which the histories or follow up were incomplete were discarded, leaving 88 cases which form the basis of this report. In this group, 98 per cent had a complete follow up and 80 per cent of the gross specimens were available for study.

Race distribution. It is generally assumed that carcinoma of the corpus uteri has a higher incidence in the colored race. Our figures, however, show that 73 per cent of the patients were white despite the fact that over one third of the total number of clinic patients are colored, and the figures show a high incidence of myomatous uteri in both races. It was noted that a high percentage of the patients with carcinoma of the uterus were obese and overweight.

TABLE I — AGE INCIDENCE

Age in years	No.	Percent
Under 30	1	1.15
30 to 40	4	4.54
40 to 50	26	29.54
50 to 60	24	27.27
60 to 70	25	28.40
70 to 80	9	9.09

Age incidence. Table I shows the age on admission of patients with carcinoma of the uterus. The youngest patient was 19, and the oldest was 77. The highest incidence occurred in the fourth and sixth decades, 22, or 25 per cent had not reached the age of 49. This corresponds with the recently published statistical study of Norris and Dunne, and illus-

trates the fact that corpus carcinoma occurs more frequently in the earlier decades than is generally assumed.

Hereditary factors. In such a small series, any factors dealing with heredity are necessarily inconclusive. A family history of cancer was obtained in 9 cases, or 12 per cent. It is of interest to note that in 5 of these cases there was a history of carcinoma on the maternal side.

Effects of gestation. The literature bears frequent reference to the influence of gestation on the incidence of carcinoma of the cervix (3, 13). The associated frequency of cervical irritation is considered a factor. In the case of corpus carcinoma, however, there is no evidence to show that gestation has any etiological significance. Our figures support this view as the cases were almost equally divided between nulligravidae and multigravidae.

Symptoms and duration. The predominant symptom was vaginal bleeding which did not correspond to any particular type. It averaged 9 months in duration prior to the beginning of treatment. Pain was a late manifestation of the disease.

Relation to menopause. Krieger in a study of 2,201 cases concluded that the average age of menopause is 47 years. Fifty-five patients in our series were past this age. Of these patients 85.5 per cent had not yet reached the menopause at 47 years and 54.5 per cent of them were still actively menstruating at the age of 50 while in 20 per cent this function persisted up to the age of 53 years. In one instance menopause was delayed until 60 years. This corresponds to the findings of Crossen and Hobbs in a similar series and illustrates the fact that late menopause is a common observation in women who develop adenocarcinoma of the corpus. These authors found that the incidence of late menopause in such cases was 4 times as high as it is in normal cases. This suggests that a woman who men-

Read before the conjoint meeting of the St. Louis and Chicago Gynecological Societies, February 13, 1937.

26 per cent in the Radiumhemmet. It will be noted that all but one of these were operable cases and only one-half were immature lesions. Three of them displayed a separate small growth at the fundus, including one which had received radiation for adenocarcinoma of the cervix at another clinic 2 years previously. We believe that the possibility of involvement of the corpus in adenocarcinoma of the cervix is not sufficiently stressed and that the fundus should always be explored.

It is recognized that any woman manifesting abnormal uterine bleeding should have a diagnostic curettage. Immediate hospitalization was often impossible in our overcrowded institution, and in consequence of this, we have recently been using the Randall biopsy cannula. This has proved an efficient and convenient method for obtaining endometrial biopsies in the clinic at the first visit. Plentiful material can be thereby removed for examination, and the patient enters the hospital with the diagnosis confirmed, ready for treatment. The possibility of missing a small localized area of cancer should always be kept in mind and a thorough curettage is indicated in doubtful and suspicious cases.

Results. Tables IV, V, and VI give the results of treatment over 10, 5, and 3 year periods, respectively. A considerable percentage of the patients came under treatment during the past 3 years and had to be eliminated from the calculations. In the operable group a 10 year survival rate of 67.7 per cent was achieved. In the inoperable group, no patients survived 10 years, and the 5 and 3 year cure rate was reduced to 20 per cent and 25 per cent, respectively. These results compare favorably with similar reported series (1) in which radiation was the only treatment used.

Table VII shows the survival rate of the body and cervix cases. All but 1 were in the operable group, yet only 1 lived 10 years, thus reducing the 5 year survival rate to 33.3 per cent.

SUMMARY AND CONCLUSIONS

1. An attempt is made to correlate the clinical and pathological findings in 88 cases of corpus carcinoma selected from the records

of the Barnard Free Skin and Cancer Hospital.

2. Seventy-three per cent occurred in the white race.

3. The highest incidence was equally divided between the fourth and fifth decades.

4. Gestation does not seem to be a factor in the predisposition to corpus carcinoma.

5. A family history of cancer was present in 12 per cent of the cases, of which more than half were directly attributed to the maternal side.

6. Late menopause is a common observation in women who develop fundal cancer.

7. There is reasonable evidence for the assumption that there is a relation between hyperplasia of the endometrium and fundus carcinoma.

8. The fundus should be explored in all cases of adenocarcinoma of the cervix.

9. Operation has been the treatment of choice. Recently use of radium before operation has been employed in the treatment of anaplastic lesions.

10. Results are calculated on the basis of 10, 5, and 3 year survivals. The poorest results were in the corpus and cervix cases, although a majority of the latter were not advanced cases.

*60.0 per cent. ‡25.0 per cent. †10.0 per cent.

Stockholm Clinic 50 per cent of these cases are found to be advanced lesions involving the entire uterus, but about 25 per cent are early, without palpable changes. At the Radium hemmet, special attention is paid to the recognition of this group of cases. This is accomplished by the routine performance of a fractional curettage of the uterus. In this procedure the cervix is curetted before dilatation, then the fundus, and then the lower segment, the curettages being collected in separate bottles. We have found it more practical to curette the lower segment of the uterus before exploring the fundus. This procedure also furnishes information on the site and extent of the lesion, which may be of practical value if the case is to be irradiated.

We have classified our cases into operable and inoperable groups, and have included the body and cervix cases in a separate group. The operability was predicated upon the extent of the disease, and in each case was verified by the chief of service.

Histological grouping. The histological classification comprises three groups. An analysis of the end results did not show sufficient divergence to warrant the separation of Group 1 cases into papillary adenoma malignum and adenoma malignum. It was therefore deemed more practical to adopt the criteria of Haagen sen (5) in preference to that of Mahle, Healy and Cutler (8) et al. Groups 1, 2 and 3 comprise the mature, intermediate and anaplastic types, respectively.

Treatment. Complete removal of uterus, adnexa, and a short vaginal cuff under spinal anesthesia has been considered the treatment of choice. Table II summarizes the classification and treatment of all cases. It shows that 73 per cent of the patients were considered operable at the onset of treatment.

TABLE VI — SURVIVAL RATE—THREE YEAR RESULTS

3	21*	3†	24

*67.4 per cent. †10.0 per cent.

Vaginal hysterectomy, under local anesthesia, was employed in a large percentage of those cases termed technically operable which otherwise would be considered inoperable on account of some intercurrent disease or debility. In these, the Schuchardt incision was at times employed to facilitate exposure. The total operative mortality was 3.4 per cent. In accordance with the improved results reported in the literature (2, 7, 17) from the use of radium pre-operatively we have latterly adopted this method in the treatment of the anaplastic lesions. The maturity of the lesion was not an important factor in the operable group, as the three histological grades were approximately equally distributed. In the inoperable group however there was a predominance of the anaplastic type of growth. The patients in this group were treated with radium alone or radium in combination with surgery. In 10 of them an intra uterine application of radium produced sufficient clinical improvement to justify subsequent operation. It is of interest to note that our indications for operability have remained approximately the same for the past 17 years and parallel that of Heyman in a series of 156 cases in which patients were treated with radiation alone.

Table III summarizes the cases of cancer of the body and cervix of the uterus. The percentage incidence was only 12.5 per cent as compared with an average incidence of

TABLE VII — SURVIVAL RATE IN CASES OF CARCINOMA OF BODY AND CERVIX OF UTERUS

THE TREATMENT OF COLON BACILLUS PERITONITIS IN RABBITS WITH ESCHERICHIA COLI ANTISERUM

H M TRUSLER, M D and JAMES M MOSS, M D Indianapolis Indiana

IN RECENT years considerable interest has been aroused in the use of serum in the treatment of peritonitis.

The preparations most commonly used have been polyvalent mixtures of various types of antisera. Weinberg (7) and Priestley (2, 3) have reported encouraging results in the treatment of diffuse peritonitis in human subjects using a polyvalent anaerobic serum, a colon bacillus serum, and a so called complementary serum against staphylococcus and streptococcus. Vincent, Weinberg and Prevot, and Ferrando have also reported the use of combinations of anticolonic bacillary serum with other serums with good results both experimentally and in clinical practice.

Although these reports are favorable, there is as yet very little experimental evidence as to the value of any type of antiserum in the treatment of peritonitis. Furthermore, since peritonitis as encountered in clinical practice is usually a mixed infection it is difficult to say which type of serum should be the most effective.

In any peritonitis resulting from the perforation of the gastro intestinal tract the colon bacillus is practically always one of the invading organisms. In an attempt to investigate experimentally the possibility of bactericidal power in a colon bacillus serum we have conducted a series of experiments using a colon bacillus antiserum in the treatment of a pure colon bacillus peritonitis in rabbits.

Experimental procedure. Twenty three rabbits were actively immunized by repeated intravenous injections of a stock colon bacillus suspension as an antigen. Agglutination titres were checked and found to range between 1:1000 and 1:10,000 after the last injection.

The 23 immune animals together with 10 controls were given an intraperitoneal injection of colon bacillus gum tragacanth peri-

tonitis producing mixture. The mixture was prepared as described by Steinberg and Goldblatt. Eleven 6 inch agar slants incubated for 20 hours were harvested in 20 cubic centimeters of saline. An equal amount of 5 per cent gum tragacanth was added to the suspension and stirred until a homogeneous mixture was obtained. The lethal dose of this preparation was found to be 2 cubic centimeters per kilogram of rabbit weight. All inoculations of this material were given intraperitoneally.

The 10 controls receiving the peritonitis producing mixture died within 14 hours. Two of the 23 immune animals died within 20 hours. The 21 other rabbits survived with no ill effects. This observation would seem to be strong evidence that the antigen injected animals had developed an active immunity against the colon bacillus.

These surviving rabbits were sacrificed for serum. Sufficient 1:20 merthiolate solution was added as a preservative to give the serum a terminal dilution of 1:100,000 merthiolate. The combined serum of the 21 rabbits was found to give an agglutination titre of approximately 1:2000.

Treatment of rabbits with colon bacillus antiserum. Ten groups of rabbits were given a lethal injection of colon bacillus gum tragacanth peritonitis producing mixture and treated with the anticolonic bacillary serum. The number of animals in each group, including 2 or more controls, varied from 3 to 6. In order to simplify the data the 10 groups of animals are combined in the following table.

A total of 24 rabbits received intravenous injections of serum. Twelve animals were given 1 injection of 5 cubic centimeters per kilogram of anticolonic bacillary serum 5 minutes after intraperitoneal injection of peritonitis producing mixture. Of these 12 animals, 5 died and 7 survived. The 12 other animals treated intravenously received 2 injections of

5 cubic centimeters per kilogram of anticoli-bacillary serum at 5 minutes and 6 hours after intraperitoneal injection of peritonitis producing mixture. Of these 12 animals, 9 survived, and 3 died.

Ten rabbits were treated *intraperitoneally* with anticolibacillary serum. Three of these received one injection of 5 cubic centimeters per kilogram of antiserum 5 minutes after peritonitis producing mixture was injected. All 3 animals died. The 7 other animals received 2 injections of 5 cubic centimeters per kilogram of antiserum 5 minutes and 6 hours after injection of peritonitis producing mixture. Only 1 of the 7 animals survived.

Thirty-one controls were used in these experiments. Eight of the controls received normal rabbit serum intravenously in similar doses to the animals treated with anticolibacillary serum intravenously, and 8 others received physiological salt solution by the same route and dosage. Fifteen others were untreated. All controls died within a period of 18 hours. Necropsy revealed a serosanguineous peritonitis in all animals that died. Rabbits weighing approximately 2 kilograms were used throughout.

Results of blood cultures. Blood cultures were taken on 15 of the rabbits which were treated intravenously with anticoli serum. All of the cultures were taken at 6 hours and previous to a second injection of serum. Five of these treated animals died and all had positive blood cultures. Of the cultures examined from the 10 surviving rabbits, 4 were positive at 6 hours, and 6 were negative. Cultures were again taken at 24 hours on the surviving animals and all were negative. All cultures were checked routinely up to 72 hours.

Blood cultures taken 6 hours after injection from 5 of the animals treated intraperitoneally were all positive for colon bacillus. All these animals died.

Blood cultures were taken on 15 of the controls. All cultures were taken at 6 hours, and all were positive. All died with a terminal septicemia.

The possibility of saving rabbits by waiting over 5 minutes before beginning specific intravenous therapy was considered. Two animals were treated at 1 hour, and 2 at 2 hours,

and 2 animals at 3 hours after intraperitoneal injection of peritonitis producing mixture. All animals received 2 injections of 5 cubic centimeters anticolibacillary serum per kilogram. The first injection was given at 1 hour, 2 hours, or 3 hours as previously designated. The second injection was given 2 hours later. All animals succumbed along with the controls.

In the preceding experiments the peritonitis producing mixture was prepared from the same strain of colon bacillus as was used to prepare the serum. We have recently treated a few animals with a concentrated anticolibacillary serum prepared as recommended by Schwartzman¹. The strain of colon bacillus used to produce peritonitis in this group of animals was isolated from the peritoneal cavity of a dog with peritonitis. The Schwartzman anticoli serum agglutinated this organism in a dilution of 1 to 200. Three series of animals were treated. Twelve animals each received two intravenous injections of 2 cubic centimeters of Schwartzman anticoli serum 5 minutes and 6 hours after injection. Six controls received the same amount of normal horse serum. Seven of the group of the 12 treated animals survived. All controls died within 16 hours as shown in Table II.

RESULTS OF STUDY

The type of peritonitis we have produced by this experimental procedure is not com-

TABLE I—RABBITS INJECTED WITH COLON BACILLUS GUM TRAGACANTH PERITONITIS PRODUCING MIXTURE, SHOWING THE EFFECT OF TREATMENT WITH COLON BACILLUS ANTISERUM

Treatment	Number rabbits	Survivals	Deaths	Mortality per cent

Survivals	7	0	
Deaths	5	6	
Mortality (per cent)	41	100	

parable to that encountered in human subjects, and we are making no effort to discuss clinical application at this time. The results we have reported would seem to indicate strongly that the serums used have a definite antibacterial action against the colon bacillus. However we are not in a position to discuss the mechanism of therapeutic action. Information gained from blood culture studies would seem to indicate that the serum acts in some manner to prevent an overwhelming terminal septicemia.

CONCLUSIONS

1 Rabbits actively immunized against the colon bacillus were able to survive in high percentage a colon bacillus peritonitis produced by intraperitoneal injection of a mixture which was fatal to controls

2 A majority of animals may be saved from diffuse bacillus coli peritonitis if treated immediately with anticolibacillary serum intravenously. The mechanism of therapeutic action apparently depends upon the fact that the serum in some way prevents an overwhelming invasion of the blood stream

THE ANATOMICAL AND SURGICAL FEATURES OF ECTOPIC KIDNEY

BARRY J ANSON, Ph D (Med Sc), and LEANDER W RIBA, M D, F A C S,
Chicago, Illinois

ANOMALOUS human organs are frequently of more than anatomical importance, since their occurrence may produce a disturbed physiology, and so ultimately require surgical removal

Among the most striking of congenital anomalies is the ectopic kidney. A kidney may be classified as ectopic by virtue of its aberrant location, its odd shape, short low pedicle, anterior pelvis or short ureter. The location has been described by Braasch as pelvic, iliac, or abdominal. The short ureter and the bizarre pelvis and calyces aid in distinguishing between an ectopic and a ptotic kidney.

On account of their varieties ectopic kidneys have received clinical consideration by many writers, excellent studies have been published by Thomas and Barton, Thompson and Pace, MacKenzie and Hawthorne, Judd and Harrington, Campbell, and many others. Ectopic kidney is not uncommon, the occurrence of 154 has been recorded in a total of 128,322 autopsies, an incidence of 1 in 833¹, but, since published accounts of excised surgical specimens are not numerous, it was considered advisable to place on record the current case of renal ectopia. The presence in the dissection laboratory of an excellent example of ectopia furnished an opportunity to follow in detail the anatomical relations of abnormal,

and associated normal, kidney—particularly those important relations having to do with the arterial supply and venous drainage.

Both the anatomical and the surgical specimens were characterized by the possession of an anterior pelvis, each was low in position with short ureter, each had a complex arrangement of renal vessels. In the anatomical specimen no hydronephrosis was evident, in the surgical specimen a marked intrarenal hydronephrosis occurred, the result of infundibular constriction produced by anomalous renal vessels.

ANATOMICAL SPECIMEN

The cadaver in which the anatomical specimen was studied was a muscular, male negro, 5 feet 11 inches in height, weighing 121 pounds (embalmed), and aged 70 years. Figures 1 through 7 show successive stages in the dissection of this specimen.

Right side The right kidney was moderately lobulated, the hilus widely open and directed anteriorly (Fig 1). The organ rested chiefly upon the psoas major muscle, extending from the level of the lower third of the second, to that of the middle of the fifth, lumbar vertebra, its upper two-thirds was therefore abdominal in position, its lower one-third pelvic. The inferior extremity covered the lumbinguinal nerve; the lateral femoral cutaneous nerve emerged from the lateral margin of the psoas major muscle at the point to which the muscle was covered by the kidney, skirting the lateral margin, at the superior pole, was the combined trunk of the iliohypogastric and ilio-inguinal. The ureter entered the broad hilus in two portions, the lower was exposed as it divided into major calyces, while the upper was concealed by the renal veins.

The upper portion of the kidney was supplied by a renal branch of the aorta which arose at the level of the lower third of the first lumbar vertebra (Figs 1 and 2). Follow-

From the Department of Anatomy and the Department of Urology, Northwestern University Medical School, contribution No 281 from the former.

¹However, the recorded incidence of ectopic kidneys noted in clinical examinations is considerably lower. Thomas and Barton 6 in 3,285 urological examinations, Thompson and Pace 1 in 10,000 admissions at the Mayo Clinic, MacKenzie and Hawthorne 13 in 15,000 examinations. Thompson and Pace suggest the discrepancy between necropsy and clinical examination was due to the fact that many ectopic kidneys were asymptomatic, special examination not indicated, and they were not diagnosed. They point out that in 52 of 88 clinical cases the diagnosis was established during the course of the urological examinations, including pyelographic studies, in the other 36, the diagnosis was made at the time of surgical exploration. An uninfected ectopic kidney with adequate urinary drainage frequently remains asymptomatic and may be discovered only during the course of an operation or at necropsy.

ing an oblique course downward and lateral ward, it appeared from beneath the inferior vena cava where the latter received the right renal vein. The artery divided into three branches, two of these pierced the renal substance on the floor of a sulcus which was continuous with the walled hilum (Figs. 2 and 2a). The backward directed stem entered the

parenchyma behind the superior extension of the hilum (Fig. 2a). The anterior one of the hilar branches gave off several twigs to the upper extremity (shown by retracting the vessel in Fig. 2a) then disappeared by passing between the tributaries of the adjacent vein, the posterior hilar branch passing behind the superior vein, coursed downward along the

Fig 4 The suprarenal veins have been transected, the gland lifted superiorly, in order to show the origin and course of the renal, suprarenal, and spermatic arteries

Fig 5 The aorta has been excised, the renal vein transected and turned aside to show the prevertebral venous plexus and its relation to the second lumbar vein

medial margin of the hilus. The lower portion of the kidney was supplied by an arterial branch derived from the hypogastric close to its origin (Figs 1 and 3), turning upward, and crossing the external iliac artery and the psoas major muscle, it pierced the lowermost portion of the inferior extremity, within a sulcus (1 centimeter in depth), continued downward from the hilus.

From the upper portion of the hilus a renal vein left the kidney (Fig 1), it was formed by the junction of two vessels which emerged from the parenchyma (Figs 2 and 2a). Into the inferior one of the two tributaries the right internal spermatic vein passed. The renal venous tributaries, in the hilus, passed to either side of the more anteriorly placed branch of the renal artery (drawn apart in Fig 2a). The anterior one of the two vessels drained chiefly the lower part of the kidney, while the posterior one carried blood mainly

from the upper portion. Veins were situated in front of, between, and behind the subdivisions of the ureter.

The right renal veins did not communicate with the ascending lumbar vein of the corresponding side, however, the lumbar system did form an anastomosis with the peri-aortic ring contributed by the renal veins of the left side.

The right ascending lumbar vein began as a tributary to the common iliac vein (Fig. 7). As it passed the fifth lumbar vertebra no lumbar vein was sent medialward to the inferior vena cava, but tributaries were received at this point from the vertebral canal. A small fourth lumbar vein was present. At the third segment a lumbar vein of fair size connected the ascending lumbar system with the inferior vena cava. Between the third and second segments the ascending lumbar vein was small, but opposite the second vertebra,

Fig 6 The ascending lumbar vein and related structure of the left side the psoas major muscle has been freed and turned aside the quadratus lumborum muscle is intact the left crus of the diaphragm has been removed to display the communication of the lumbar with the azygos system of veins The second lumbar vein here indicated by arrow is the vessel shown in Fig 5 which communicated with the circum aortic ring

Fig 7 The ascending lumbar vein and the lumbar arteries of the right side with related structures the crus of the diaphragm partially covers the first lumbar vertebra the quadratus lumborum muscle (the psoas major removed) the iliac muscle below the brim of the greater pelvis The lumbar plexus of nerve has been removed

the lumbar vein again enlarged, in addition to tributaries from the psoas major muscle and the vertebral plexus two tributaries were received from the posterior abdominal wall. It was with the second lumbar vein that one of the tributaries of the retro aortic venous plexus communicated. Continuing cranial ward, the ascending lumbar vein passed beneath the crus and became continuous with the azygos vein in the thorax (Fig 5).

The arrangement of the lumbar arteries was somewhat irregular. The fifth lumbar artery

terminated in the fine twigs on the vertebra, the fourth was wanting, the third the largest of the group sent branches into the inferior three intervertebral foramina the second and first supplied unusually prominent branches to the musculature of the back. No segmentally arranged branches of the aorta were sent to the kidney (Anson Richardson and Visceral 1936 Figs 8 to 11).

Left side. The left kidney was normal in form and in position (Fig 3) its inferior extremity did not quite reach the level of the

crest of the ilium, extending from the middle of the twelfth thoracic to the lower third of the third lumbar vertebra.

The exposed course of the single renal artery was very short. It arose from the aorta opposite the upper third of the first lumbar vertebra, appearing from beneath the inferior extremity of the suprarenal gland, the artery quickly divided into two branches which entered the hilus of the kidney (Figs 3 and 4). The single renal vein was a vessel of large size and transverse course, it crossed the aorta just beneath the origin of the superior mesenteric artery, at the level of the intervertebral fibrocartilage between the first and second lumbar vertebrae. It received on its cranial margin an inferior phrenic vein (which had suprarenal tributaries) and a suprarenal vein, just lateral to the suprarenal vein a pair of internal spermatic arteries arched over the renal vein. On its caudal margin the renal vein received an internal spermatic, formed by the junction of two tributaries, lastly, a small vein from preperitoneal tissue surrounding the aorta.

A prevertebral venous plexus occurred in association with the left renal vein (Fig 5). The plexus, imbedded in the thin stratum of connective tissue which intervenes between the great vessels and the vertebral column, was so placed that its existence would not be suspected by the surgeon, yet, in a current study of the renal and suprarenal territory, it was found that a comparable set of intercommunications is of frequent occurrence.¹

The plexus began superiorly in two small veins, one from each crus of the diaphragm (Fig 5 *a* and *b*), at their junction they formed a hiatus for the passage of a branch of the first lumbar artery. Widening somewhat, this channel received on its inferior aspect a communicating vein from the ascending lumbar system of the opposite side. This communicating vein (second lumbar of the right side), and the anastomotic vessel from the plexus (Fig 5 at *c*) together joined the inferior vena cava

(Fig 2, at *c*). Next, the retro-aortic plexus received a small parietal vein, of medial course, from the surrounding connective tissue (Fig 5, *d*), then, superiorly, a vein from the left crus of the diaphragm (Fig 5, *e*). Adjacent to this diaphragmatic vein were two small renal tributaries (Fig 5, *f*), which, en route to the common venous channel from the superior part of the hilus, surrounded the renal artery. On the inferior aspect of the channel a large vein, the second lumbar, entered from the psoas major muscle (Fig 5, *g*). The lumbar vein emerged from the vertebral margin of the left psoas major muscle opposite the middle of the second lumbar vertebra, its drainage was not only muscular, but meningeal and osseous as well (Fig 6 *g*). In prevertebral position its shape was that of a letter J, from the lowermost part of its curve a communicating branch was sent obliquely downward and to the right to bring this post-aortic group of veins once more into connection with the inferior vena cava (Fig 5, *h*), the latter anastomosis established at the level of the middle of the third lumbar vertebra. The venous vessels just described passed behind the aorta, the renal vein proper passed in front (Figs. 3 and 4), together they surrounded the aorta to form a circum-aortic venous ring¹. They communicated at a point 1 centimeter medial to the hilus of the left kidney.

The renal drainage on the left side was brought into communication with the ascending lumbar system by means of this lumbar vein (Fig 6, at *g*). The ascending lumbar vein itself was divided into two portions one inferior, one superior to, the third lumbar vertebra (Fig. 6), the drainage passing inferiorly and superiorly from this line of division. The superior portion was, as already mentioned, related to the renal vein. The second lumbar vein passed deeply into the psoas major muscle, attaining the level of the roots of the transverse processes. At the foramen between the second and third lumbar vertebrae it received a meningeal tributary, and in that locality several muscular tributaries from the psoas major; from above, one lumbar vein entered the ascending lumbar, passing superiorly, it became the hemi-azygos

¹In a comprehensive study of the renal and suprarenal vessels by Anson, Pick, and Beaton, 128 cadavers have been examined to date, in 15 of these (11.7 per cent), the circum-aortic ring occurs, not infrequently, and in a manner to be described in a subsequent publication, the deeper one of the transverse veins communicates with a prevertebral venous plexus, and with lumbar veins (Fig 5). These features have been described and figured by Lejars (1888), recently by Odgers (1931), Fagarsanu (1938), and others.

Fig 8 Right retrograde pyelogram showing the renal pelvis of bizarre form the dilated minor calyces and the short ureter

The veins inferior to the level of the third lumbar segment drained caudalward and were not segmentally arranged, interrupted between the levels of the second and third lumbar vertebrae, the meningeal veins emerging from the lower lumbar vertebrae (third, fourth, fifth), formed a venous trunk into which passed also muscular tributaries from the psoas major muscle the trunk emptied into the common iliac vein into which latter also drained a second vein from the fifth lumbar level. The corresponding arteries were derived from two sources the ilio-lumbar branch of the hypogastric (inferiorly), the third lumbar artery (superiorly) no segmental arteries occurred at the fourth and fifth.

From this description it should be clearly evident that the parietal and visceral venous channels are intimately related. Thus, beginning with the pelvic level in the specimen described, the iliac veins received vessels from the pelvic organs muscles, and skeleton by means of the lumbar veins (Figs 6 and 7)

blood was brought to the inferior vena cava, not only from the lumbar skeleton and musculature but from the spinal cord and its meningeal investments, additionally these veins received parietal rami (Fig 7) from the retroperitoneal connective tissue, and their major trunk the ascending lumbar vein, communicated with the common iliac vein (Fig 6). In the subphrenic region, the chief caval tributaries were, of course, received from the kidney, one of these passed anterior to the aorta (Fig 4) the other posterior to that axial vessel (Fig 5). The pre-aortic vessel drained not only the kidney, but also the testis, supra-renal gland, retroperitoneal tissue, and diaphragmatic musculature. The retro-aortic vein, through its plexiform arrangement of tributaries drained the muscle constituting the crura of the diaphragm the areolar tissue housing the great vessels, and the upper extremity of the kidney (by means of minute veins), it communicated directly with the ascending lumbar system by means of the second lumbar vein. Through the continuity of the lumbar with the azygos system (Fig 6), communication was established between the pelvic the abdominal parietes and contents and the thoracic wall and serous membranes.

The importance of this anastomosis in the spread of infection through the entire renal and deep lumbar areas is obvious. The rich set of anastomoses may account for the spread in cases reported by other investigators. Thus Israel (1911) and Bavard (1921) noted that fatal tuberculous meningitis may follow nephrectomy for tuberculosis. Another fatal case was recently reported by Turner, death occurring 36 days postoperatively. Autopsy revealed no tubercular foci in the nephrectomy area. In the presence of rich venous anastomoses direct intrameningeal contamination could easily occur as the result of renal manipulation incidental to nephrectomy.

SURGICAL SPECIMEN

An ectopic kidney is subject to all the diseases which may assail a normal kidney in addition as a result of its anomalous development aberrant vessels, constrictions, and adhesions may predispose to malfunction and pathological changes. When urinary drainage

Fig 9 Excised right kidney (same as Fig 8) with anterior pelvis (injected with wax) Showing the bifid pelvis, the numerous hilar arteries and veins which course along each side of the infundibula (see arrangement of the vessels in Fig 1). Abbreviations a, artery, v, vein

Fig 10 The dorsal half of the same kidney, showing on the cut surface, the cavitation at the minor calyces

is incomplete, symptoms of indefinite low abdominal pain and backache occur, frequently accompanied by hydronephrosis, infection, or calculus

When indicated, ectopic kidneys causing symptoms are preferably treated by nephrectomy. In 21 cases with ectopic kidney treated surgically, reported by Thompson and Pace, the kidney was removed in 17. MacKenzie and Hawthorne performed 7 nephrectomies and 1 exploratory operation for neoplasm in 13 cases. In Judd's series of 19 pelvic kidneys only 10 required surgery. Thomas treated his 6 ectopic kidneys surgically, presumably by nephrectomy.

In the present case, renal ectopia caused distressing vague abdominal pain and backache. Nephrectomy was necessary owing to the unusual relationship of the renal vessels to the infundibula.

C J, female, aged 27 years, entered the Passavant Memorial Hospital January 31, 1936, complaining of vague right abdominal pain and backache associated with frequency, urgency, dysuria, and nocturia for 8 years. The appendix had been removed for the above complaint 2 years before. There was a

history of measles, mumps, whooping cough, chicken pox, malaria, and scarletina during childhood. The general physical examination was essentially negative except for an asymptomatic scoliosis. Complete urological investigation revealed a low lying, fixed, uninfected right kidney with good function. Right retrograde pyelogram (Fig 8) revealed a bifid pelvis, dilated minor calyces and a short ureter. The left kidney was thought to be normal. The bladder and urethra revealed a low-grade chronic infection. The bladder urine contained pus cells (grade II), motile bacilli and motile trichomonas. The culture revealed bacillus coli. Under gas anesthesia on June 9, 1936, an extraperitoneal right nephrectomy was performed. The postoperative convalescence was uneventful and the patient experienced complete relief of pain in the right abdomen and back.

The surgical specimen (Figs 9 and 10) measured 7 by 12 centimeters. The kidney was unusually flat and oval in shape, the renal pelvis was bifid and anteriorly placed, the hilus open and unobstructed. There were 4 separate arteries and veins. Surfaces made by cutting exposed the dilated minor calyces, appearing as cavities measuring 1 to 2 centimeters in diameter. In the anomalous pedicle, due to early division of the arteries and veins, the vessels surrounded and passed close to the infundibula as they emerged from the renal parenchyma. This vascular arrangement produced a "vise-like" constriction sufficient to produce the intrarenal hydronephrosis. Two veins entered the lateral margins of the kidney,

although their origin was not identified at the time of operation it is reasonable to suppose that they were related to either iliac or hypogastric veins (see arteries Figs 1 and 2).

The authors are indebted to Earl W. Cauldwell and Hugh Wilson for the careful preparation of the anatomical dissections.

PRIMARY RETICULUM CELL SARCOMA OF BONE

FREDERIC PARKER, Jr, M D, and HENRY JACKSON, Jr, M D, Boston, Massachusetts

THE type of primary bone tumor to be described in this paper apparently constitutes a definite group which has not been recognized in the past. No provision for this group has been made in the classification of the Registry of Bone Sarcoma of the American College of Surgeons. In the Registry cases included in this present study the diagnosis of primary reticulum cell sarcoma was first suggested in 1931 (Registry No 1059). It was not until 1936 that an initial diagnosis of primary reticulum cell sarcoma was made (Registry No 1992). Prior to this date these cases had been variously classified as Ewing's sarcoma, Hodgkin's disease, lymphosarcoma, osteogenic sarcoma, leucosarcoma, or as inflammation. In view of these facts it seems worth while to emphasize the characteristics of this type of bone tumor and describe its clinical course, especially as this neoplasm seems to have a more favorable course than its appearance would indicate.

From our own material and from the Registry of Bone Sarcoma, we have collected 17 cases of primary reticulum cell sarcoma of bone. Of these, 10 were male, 7 female. The age distribution differs materially from that of the generalized form of reticulum cell sarcoma, which is primarily a disease of middle and old age—84.5 per cent of all cases occurring after the age of 40 and less than 1 per cent being found under 20 years of age. As will be seen from Table I, 77 per cent of the primary reticulum cell sarcomas of bone occurred under the age of 40 and 35 per cent under the age of 20.

In the generalized form of the disease, metastatic bone lesions occur most commonly in the vertebræ and skull. In sharp contrast, primary reticulum cell sarcoma of bone is found to be present most frequently in the long or flat bones (Table II).

From the Thorndike Memorial Laboratory, the Second and Fourth Medical Services (Harvard), the Mallory Institute of Pathology, Boston City Hospital, the Department of Medicine, Harvard Medical School, Boston, the Collis P. Huntington Memorial Hospital, Harvard, and the Pondville Hospital, Wrentham.

Clinically, the onset is similar to that of other primary bone sarcomas, namely, with pain not relieved by rest. Pain localized at the site of disease or referred to the joint nearest the tumor was the first symptom in 13 cases, in 3, a pathological fracture brought the patient to the physician, in 1, a painless swelling of the bone and surrounding soft parts was the chief initial complaint. An obvious and tender swelling of the affected part was noted in 8 instances. The general health of the patient was good in all but 2 cases, in these there had been considerable loss of weight and strength. In none was fever noted, in no instance were abnormalities found in the peripheral blood picture. The few blood calcium and phosphatase determinations which were done were within normal limits, but the number of determinations were too few to be significant. A history of injury preceded the initial symptoms in 5 cases, but we have no good evidence that trauma is actually of etiological importance. It is more probable that a minor injury brought on symptoms in an already diseased bone or that a previous injury was recollected by the patient when symptoms of importance supervened. Perhaps the most important clinical feature is that an extensive, painful, destructive process in a long bone is found in a patient whose general condition is good. In no other bone sarcoma is the contrast between the comparative well-being of the patient and the size of the lesion so marked.

TABLE I — AGE DISTRIBUTION OF PRIMARY RETICULUM CELL SARCOMA OF BONE

Age	No cases	Age	No cases
0-9	0	30-39	4
10-19	6	40-49	2
20-29	3	50-59	2

TABLE II — BONE INVOLVED IN PRIMARY RETICULUM CELL SARCOMA OF BONE

Location	No cases	Location	No cases
Femur	5	Humerus	3
Clavicle	4	Scapula	1
Tibia	3	Mandible	1

although their origin was not identified at the time of operation it is reasonable to suppose that they were related to either iliac or hypogastric veins (see arteries Figs 1 and 3)

Fig 6, left Registry Case No 564 Gross specimen, humerus

Fig 7 Registry Case No 83 Gross specimen, humerus

We wish, however, to emphasize the importance of early diagnosis and treatment, for by these means only can one expect to obtain the best results. In 1 instance, signs and symptoms definitely pointing to a tumor of the femur had been present for a year and 4 months before amputation, and the condition had been variously diagnosed as tuberculosis and as arthritis. At the time of operation, the tumor had reached massive size and inguinal lymph nodes had appeared. The patient was dead 3 months later. It is not improbable that, had an accurate diagnosis been made by biopsy at an earlier date, the results would have been better.

The x-ray appearance is by no means pathognomonic. The disease is most frequently seen in the ends of the long bones and extends from the metaphysis into the diaphysis (Figs 1 to 4). In 3 cases the middle of the clavicle was the site of the tumor, in 1 the middle of the mandible was the point of origin

In general, x-ray examination shows chiefly bone destruction, and to a much less degree new bone formation, sometimes incident to a pathological fracture. In early cases there may be only mottled bone destruction in the medulla (Figs 1 and 2). In 1 early case, very fine striations extended from the irregularly thickened cortex and periosteum into the adjacent soft tissue. In the more advanced cases, there is extensive involvement of bone with marked osteolysis and only moderate or no osteogenesis (Fig 3). Pathological fracture (Fig 4) occurs occasionally and in those cases callus formation may complicate the picture. There is often fragmentation of the cortex and a widening of the shaft as if from an expansive tumor pressing from within outward. Periosteal thickening may be seen both early and late. Invasion of surrounding muscle is common. The disease has been mistaken by radiologists for osteomyelitis, osteogenic sarcoma, Ewing's tumor, and Hodgkin's disease.

Fig 1 Registry Case No 1992 Roentgenogram of femur
Fig 2 Registry Case No 1900 Roentgenogram of tibia
Fig 3 Registry Case No 83 Roentgenogram of humerus

In no other bone tumor may the lesion be so extensive and at the same time be so amenable to appropriate treatment

The disease had existed, as suggested by the symptoms for many months in several cases before the services of a physician were sought. In 7 cases, symptoms had been present for a year or more before treatment, and yet 5 of these patients are alive and apparently well from 3 to 14 years later. This very fact attests the comparatively benign nature of what appears roentgenographically clinically, and histologically to be a highly malignant tumor.

Fig 4 Registry Case No 564 Roentgenogram of humerus

Fig 5 Registry Case No 564 Photomicrograph Hematoxylin eosin stain $\times 927$

Lymphosarcoma The type cell with its round nucleus, scanty cytoplasm, and spherical shape should offer no difficulty. In our experience, true lymphosarcoma of bone is extremely uncommon.

Ewing's sarcoma Reticulum cell sarcomas have been most frequently erroneously diagnosed as Ewing's sarcoma. In the latter, the uniform character of the cells and of their nuclei, the arrangement in strands and cords, and the distribution of the reticulum are diagnostic features. In Ewing's sarcoma, the reticulum surrounds groups of cells, while in reticulum cell sarcoma not only does the reticulum surround groups, but it also runs between the individual cells.

Osteogenic sarcoma Some of the reticulum cell sarcomas have been diagnosed as atypical osteogenic sarcomas. The lack of any tumor, bone, or cartilage formation, the absence of osteoid tissue, and the morphology of the tumor cells should serve to exclude this diagnosis.

Inflammation The diagnosis of inflammation was made in 2 cases in the Registry. The presence of the large mononuclear cells and lymphocytes with, in addition, necrosis, have proved misleading. In one of our own cases, the infarct type of necrosis and marked cellular infiltration of the vessel walls led to the incorrect diagnosis of syphilis.

Since there have been no autopsies on the cases of reticulum cell sarcoma described, it might be argued that we are not justified in terming this group primary reticulum cell sarcoma of bone. However, the complete lack of evidence of a primary tumor elsewhere and the favorable course following amputation argues for the primary nature of this tumor. It is common knowledge that a small and, indeed, unrecognizable primary tumor, as in carcinoma of the breast or bronchus, may give rise to large metastatic lesions, but it would be most unusual to have a secondary lesion of massive size arise and still have the primary tumor remain silent 14 years after the amputation of the metastatic lesion, as in Registry Case No. 564. Furthermore, those patients who had inadequate treatment have shown evidence, before death, of metastases rather than the appearance of a primary tumor concealed, for a time, in an internal organ. Generalized lymph node

and pulmonary metastases were found in one case. In another, a second tumor appeared in another long bone. In a third case, not included in the present series because we have only a lymph node biopsy (there had been a destructive lesion of the femur for 2 years prior to this biopsy), there appeared, before death, generalized lymphadenopathy, splenomegaly, hepatomegaly, and destructive lesions in the radius, humerus, and pubis.

The following cases illustrate the course of the disease.

W B, a single man, aged 44 years (Bone Sarcoma Registry No. 564), was admitted to the Massachusetts General Hospital October 1, 1924. His past history was uneventful.

Since January, 1924, he had experienced moderate pain in the right upper arm. In May, 1924, while playing baseball, he fractured his right humerus. An x-ray film taken at this time showed no evidence of tumor. The bone, however, did not unite well and in August, 1924, the patient noticed a swelling of the middle of the right upper arm. Although the pain decreased, the tumor increased in size. An x-ray examination on October 2, 1924, showed destruction of the humerus throughout nearly its entire extent (Fig. 4). There was little if any new bone formation although there had been 6 months before a fracture in the midportion. The new-growth extended nearly to the head of the humerus. The proximal portion of the ulna appeared to be involved by a similar process.

On October 9, 1924, a shoulder joint amputation was performed. In 1924, this tumor was diagnosed as medullary sarcoma and as osteolytic sarcoma. In 1925, a diagnosis of osteogenic sarcoma was made, and in 1930 the condition was believed by one reviewer to be a benign giant cell tumor. In 1934, it was first suggested that the tumor was a reticulum cell sarcoma, the diagnosis being based on the criteria set forth in this paper.

Convalescence was uneventful and the patient remained entirely well until October, 1931, when a tumor developed in the amputation scar. This mass was excised and showed the same histological picture as did the original bone tumor. The patient has remained well and active to date, January, 1938, 14 years from the onset of symptoms.

That the disease was most extensive at the time of operation is attested by Figure 6, a photograph of the gross specimen removed in 1924.

W S, a boy, aged 15 years (Registry No. 1663), aside from the usual childhood diseases, had been quite healthy. In the spring of 1927, he noticed a tender swelling in the region of the left knee. Radium was applied (in unknown doses) and the pain

Fig 8 Registry Case No 1762 Reticulum stained by Foot-Hortega silver method $\times 283$

Fig 9 Registry Case No 1762 Tumor growing in vein Wright elastic tissue stain $\times 57$

In gross appearance, the tumor varies considerably. In early cases the medullary cavity is seen to be invaded by pinkish gray granular tissue. In more advanced cases, the bone destruction and soft tissue involvement referred to elsewhere is obvious. The tumor in these instances is usually firm, smooth, and glistening; more rarely it is soft and friable. The color is variously described as pale, white, pinkish gray and gray white. Areas of necrosis are frequent and may merge into cavities resembling osteomyelitis.

The type cell (Fig 5) is identical with that of reticulum cell sarcoma of lymph nodes and other tissues. The nature of this cell and the histogenesis of reticulum cell sarcoma in general will be taken up in a subsequent paper. The cell is larger than a lymphocyte. The nucleus, which is from $1\frac{1}{2}$ to 2 times larger than that of a lymphocyte, varies in shape from round to oval; frequently it may be indented or lobulated. In the cells of well differentiated tumors, the chromatin is finely divided and scattered. In the more anaplastic it tends to be coarser and nucleoli may be prominent. The cytoplasm varies in its staining reaction from acidophilic to basophilic and may be considerable in amount in relation to the nucleus. The cell varies from round to oval to elongated. Evidence of ameboid activity, as indicated by shape of cell and its nucleus, is frequently present and is indeed a characteristic feature. Binucleate forms occur, but true tumor giant cells do not. Mitotic figures are often present in large number.

The stroma varies in amount from delicate strands of collagen to dense bundles. When stained in order to bring out the reticulum, this is found to occur running in delicate threads and strands around groups of tumor cells and also between individual cells (Fig 8).

A fairly common feature of these tumors is the growth of the cells in the walls of small veins (Fig 9). In such veins the endothelium is lifted and the lumen is encroached upon and distorted by the tumor cells in the intima. A similar involvement of arteries or arterioles has not been seen. Necrosis of the infarct type is often a prominent feature. Scattered foci of lymphocytes are frequently found to be present.

Complete destruction and obliteration of the normal constituents of the marrow is constantly found. Osteolysis is often a prominent feature. The tumor cells do not form bone, but new bone formation by the stroma does occur. Invasion of the surrounding soft parts is common.

Reticulum cell sarcoma must be differentiated from the following conditions:

Hodgkin's disease. The granulomatous form with sclerosis, necrosis, eosinophils, and Reed-Sternberg cells should present no difficulty. The sarcomatous form in which the majority of the cells are of the mononuclear type may simulate closely anaplastic reticulum cell sarcoma, but the presence of even an occasional typical Reed-Sternberg cell should serve as a differential point. Primary Hodgkin's disease of bone we believe to be very rare indeed.

Histologically, the tumor cells have round, oval, indented, or lobulated nuclei which are nearly twice the size of that of a lymphocyte. The chromatin is scattered and the cytoplasm is considerable in amount.

In spite of its apparently malignant nature, the tumor is amenable to appropriate treatment, 13 of the 17 cases being alive from 6 months to 14 years from the initial symptom. Seven of these patients have been apparently free from disease 10 or more years.

Five patients were treated by amputation alone. Of these, 2 are dead, 3 are alive from 3 to 11 years from onset. We have already referred to a possible explanation for the deaths in this group.

Three patients were treated by radiation alone. Of these 1 is dead, 2 are alive from 1 to 3 years later, but in each there is still neoplastic disease.

Of the 9 patients treated by amputation and radiation, 8 are alive from 6 months to 14 years from onset.

From a consideration of the cases presented, the best procedure would appear to be early diagnosis by biopsy followed by immediate amputation and radiation.

ABSTRACT OF CASE HISTORIES

Be, male, aged 31 years. In June, 1926, the patient sustained a minor injury to the knee. During the following summer there was gradually increasing pain and swelling of the knee. In October, 1926, an x-ray film showed a destructive lesion of the lower end of the femur with some periosteal thickening. In November, 1926, a biopsy was done and the following diagnoses were made: sarcoma, myeloma, syphilis, chronic inflammation. On December 17, 1926, a mid thigh amputation was performed. The patient died September 10, 1927, with generalized lymph node metastases and metastases in the spinal canal and lung.

Sr, male, aged 35 years. In February, 1924, the patient felt something snap in his shoulder and he was incapacitated for a few days. In January, 1925, he felt another sharp pain in his left shoulder. Gradually swelling appeared over the left upper scapula. On April 1, 1925, an x-ray examination showed a destructive process in the scapula involving the spine and the acromial process. A diagnosis of osteomyelitis or sarcoma was made. Radium needles were inserted, the mass, however, continued to grow and the patient died October 24, 1925, following a massive hemorrhage from the original tumor.

Registry No 1951, female, aged 48 years. In the spring of 1934, the patient noticed some stiffness in

her left knee. In August of the same year, there developed considerable pain and swelling of the knee. In October, 1934, an aspiration biopsy was done and a tentative diagnosis of tuberculosis was made. By July, 1936, the pain had become much worse and the patient was put in a Thomas splint with traction. In January, 1936, there had developed an enormous swelling of the lower half of the thigh and enlarged inguinal lymph nodes. A hip joint amputation was done and a diagnosis of Ewing's tumor was made. X-ray therapy was instituted. The patient died April 26, 1936, with pulmonary and lymph node metastases.

Registry No 83, female, aged 12 years. In February, 1920, the patient sustained a pathological fracture of the left humerus. Examination shortly thereafter showed a lobulated tumor of the upper half of the humerus. The mass was red, tender, and fluctuant. An x-ray examination showed a destructive process of the upper half of the left humerus and a pathological fracture. A shoulder joint amputation was done and a diagnosis of osteogenic sarcoma was made. The patient was lost sight of and died April 24, 1932, from a presumed "tumor of the right knee."

Bu, male, aged 14 years. H H No 37-1599. In July, 1937, the patient sustained a mild injury to the right lower jaw. In September of the same year he noticed a painless lump in the middle of the right mandible. An x-ray examination showed an irregular increase of density of the right mandible and fine striations radiating into the surrounding soft tissues. On December 31, 1937, the right half of the mandible was resected and the patient given 1500 r units high voltage x-ray. The tumor was diagnosed as a reticulum cell sarcoma. The patient was alive and well March 7, 1938.

Registry No 1992, female, aged 15 years. In the winter of 1935-1936, the patient noticed an intermittent pain in her right knee with some limitation of motion of the knee. On August 4, 1936, the general physical examination was normal. There was some thickening over the lower end of the right femur with slight limitation of motion of the knee. An x-ray picture showed a mottled destruction in the lower 2 inches of the femur without expansion and with little if any periosteal reaction. From a biopsy specimen on July 31, 1936, a diagnosis of reticulum cell sarcoma was made. The patient was given high voltage x-ray with symptomatic relief. The x-ray picture, however, remained essentially the same. The patient's condition was essentially unchanged August 5, 1937.

Registry No 1867, female, aged 58 years. In June, 1934, the patient noticed a pain in the left chest which finally localized in the left sternoclavicular joint. In February, 1935, a tumor appeared at the inner end of the left clavicle. On June 5, 1935, the general physical examination was normal. There was an egg-sized tumor of the inner end of the left clavicle. A biopsy was performed and the lesion was variously diagnosed as mixed cell osteogenic sarcoma

and swelling completely receded for a period of 6 months. All symptoms then returned and the patient lost 30 pounds in weight. An x ray examination on March 25, 1929 showed an irregular lesion involving the cortex and medulla of the proximal third of the shaft of the tibia. The lesion was mottled in appearance due to irregular zones of bone destruction intermingled with dense zones of new bone formation. The cortex was roughened and the periosteum lost in a large soft tissue swelling enveloping the knee. A diagnosis of Ewing's tumor was made and amputation was done March 26, 1929. This specimen was diagnosed in 1934 as Ewing's sarcoma. In 1936 as questionable reticulum cell sarcoma and as Ewing's tumor. In 1936 a definite diagnosis of reticulum cell sarcoma was made. Recovery was uneventful, and the patient is well and free from symptoms or signs of disease at present 10 years after the onset of the tumor.

It is impossible at present to conclude what the best form of treatment is. Amputation followed by radiation to the adjacent lymph nodes, however, would appear to give the best results. In one instance (Registry Case No 1523) excision appeared to be adequate, but we believe that amputation should be done whenever possible. In addition, radiation would seem advisable. A biopsy of the lesion may safely be done prior to amputation, but it should be emphasized that only by careful microscopic examination of a properly fixed and stained section can the correct diagnosis be made.

Three cases (Registry Nos Sr, 1992, 1867) received radiation only. One of these died in less than 2 years with a massive hemorrhage from the original tumor. Two cases are still alive, in one (Registry No 1992), the original tumor by x ray examination seems to be essentially unaltered a year later, in the second (Registry No 1867), a pathological fracture had just appeared in another long bone after 3 years.

Two cases (Registry Nos 1663, 1723), had initial radiation with complete disappearance of both signs and symptoms, but, in each instance, the tumor recurred locally within 6 months. Amputation was then done and the patients are both alive and apparently free from disease 10 and 12 years from onset.

One case (Registry No 1909) was given x ray therapy for 5 years, but the symptoms steadily increased and lymph node metastases appeared. Amputation was then performed,

and the patient is living and apparently well 14 years from onset.

In 6 cases, amputation was followed by x ray therapy. In 4, radiation was given immediately after amputation. Three of these are alive and well respectively 8 months (Bu), 8 years (Registry No 1932), and 10 years (Registry No 1039) from onset. The fourth patient (Registry No 1954) died in 2 years of pulmonary and lymph node metastases after the amputation of a massive tumor of the femur which had been present for over a year and from which the inguinal lymph nodes had already become involved before operation. In another instance (Registry No 547), excision of the tumor was followed 8 months later by a questionable metastasis in another long bone which was subjected to radiation therapy. The patient is alive and well 14 years later. In the sixth patient (Registry No 564), a new neoplastic lesion appeared in the amputation scar after 7 years. This mass was excised and given radiation treatment as well. The patient is alive and well 14 years from the first symptom.

In 5 cases amputation only was done. Of these, 1 (Be) died somewhat over a year later following a mid thigh amputation for a lesion of the femur. A hip joint amputation would probably have been preferable. One patient (Registry No 83) died 12 years from onset with a questionable metastasis in another long bone, no further follow up having been made.

The 3 other cases (Registry Nos 1762, 1523, MC) are alive from 3 to 12 years from onset. From a consideration of these data it would appear that amputation plus radiation offers the best chance of cure.

SUMMARY

Seventeen cases of primary reticulum cell sarcoma of bone are presented.

The disease may be seen at any age, usually occurs in the long or flat bones and in spite of involving a given bone very extensively usually leaves the patient in good general condition.

Röntgenographically the lesion is primarily destructive, often massive. In the early stages diffuse medullary mottling may be the only sign. Later the expansive tumor may give rise to fragmentation of the cortex and pathological fracture.

February, 1923, there appeared a swelling of the middle of the right clavicle. The patient lost 30 pounds in weight. On June 20, 1923, the clavicle was excised and x-ray therapy was given to that region. This tumor was diagnosed as Ewing's tumor (1925), endothelioma (1930), and reticulum cell sarcoma (1934). In February, 1924, he experienced some pain in the shaft of the ulna. An x-ray film showed a questionable lesion in the ulna. X-ray therapy was given. On April 28, 1936, the patient was found to be alive and well, having completely regained his weight.

Registry No 1932, male, aged 36 years. In late January, 1930, the patient experienced considerable pain in the right hip with resulting limitation of motion on that side. April 3, 1930, the patient fell and fractured the neck of his right femur. The resulting pain and disability were sufficient to warrant a resection of the end of the femur. The specimen removed, B C H S-30-1139, showed reticulum cell sarcoma. Following operation, the patient was given high voltage x-ray therapy for a period of 4 months. The patient was alive and well with no signs of recurrence in April, 1938.

and reticulum cell sarcoma. An x ray examination showed a pathological fracture of the clavicle, bone destruction and expansive tumor. High voltage x ray therapy was given with symptomatic relief. On August 4, 1937 there appeared a pathological fracture of the humerus apparently due to a metastatic tumor.

Registry No 1762 male, aged 29 years. In the summer of 1933 the patient noticed transient pain in the left knee. In the winter of 1933-1934 the pain became worse. In April 1934 the tibia was incised and a diagnosis of osteomyelitis was made. A discharging sinus resulted and in May 1934 some gelatinous material was obtained from which a diagnosis of osteomyelitis was made. In September 1934 a large fungating tumor at the upper end of the tibia appeared and a diagnosis of Ewing's sarcoma was made. Amputation was done on September 19, 1934 at junction of middle and lower thirds of femur. Patient alive and well in February, 1937.

M C female aged 24 years. M G H 33 2637. In December 1932 the patient noticed slowly increasing pain in the right knee. In October, 1933 there was diffuse swelling in the lower third of the right femur. An x ray picture showed thickening in the lower part of the femur with diffuse mottling of the medullary cavity and periosteal thickening. A mid thigh amputation was done October 16, 1933. The patient was reported alive in March, 1938.

Registry No 1059 female aged 18 years. In June 1927 the patient felt listless and had been losing some weight. There was a painful swelling of the left clavicle near the sternum. A physical examination showed a tumor of the inner end of the clavicle and a diagnosis of cyst was made. The clavicle was incised and the necrotic material removed. A diagnosis of osteomyelitis was made. On October 4, 1927 the microscopic sections of material removed were reviewed and a diagnosis of Ewing's sarcoma made. The clavicle then was completely excised. In 1930 this tumor was variously diagnosed as Ewing's sarcoma atypical sarcoma osteogenic sarcoma and giant cell tumor. In 1931 a diagnosis of reticulum cell sarcoma and lymphoblastoma was made. In November, 1927 the patient was given x ray therapy over the region of the clavicle and was reported alive and well August 28, 1937.

Registry No 1663 male aged 13 years. In March 1927 the patient fell and bumped his knee. Following this there was pain, tenderness and slight swelling in the left knee. During the summer of 1928 radium was applied with the improvement of symptoms and the disappearance of the swelling. The tumor however recurred and the patient lost 30 pounds in weight. On March 25, 1929 an x ray film showed in the proximal two thirds of the tibia an irregular lesion involving both the cortex and medulla. The periosteum was lost in a huge soft tissue mass. A diagnosis of Ewing's tumor was made. An amputation was done March 26, 1929 with an eventful recovery and a return to normal weight. The patient was alive and well March 10, 1937.

Registry No 1523 female aged 58 years. On December 15, 1925 the patient fell and struck her right shoulder with resulting severe pain and swelling. An x ray examination on January 11, 1926 showed a pathological fracture of the surgical neck of the right humerus with a destructive process of the upper third of the right humerus, an elevation of the periosteum, and some thickening of the surrounding soft tissues. On January 25, 1926 the upper third of the humerus was excised. This tumor has been variously diagnosed as undifferentiated sarcoma (1933), leucosarcoma (1933), reticulum cell sarcoma (1934), lymphoblastoma (1934), reticulo endothelioma (1934). The patient was alive and well September 21, 1937.

Registry No 1723 male aged 34 years. On August 8, 1925 the patient sustained a pathological fracture of the right clavicle. An x ray picture showed a pathological fracture and a destructive lesion of the outer and middle thirds of the clavicle and a large soft tissue mass. X ray therapy was given with the disappearance of the tumor and a union of the fracture. The tumor however, recurred and on March 26, 1926 the clavicle was excised. This tumor was diagnosed as Ewing's sarcoma (1934), reticulum cell sarcoma (1935) and lymphoblastoma (1935). The patient was alive and well August 14, 1937.

Registry No 1909 male aged 26 years. In August 1923, the patient noticed tenderness, edema and heat over the upper tibia. A diagnosis of osteomyelitis was made. On June 28, 1930 a biopsy was done and a diagnosis of sarcoma made. High voltage x ray was given but a lymph node appeared in the groin in November 1931. This was excised December 4, 1931 and a diagnosis of lymphoblastoma made. X ray therapy was continued but the pain and tenderness increased and on August 16, 1935 a mid thigh amputation was done. The patient was alive and well May 22, 1937.

Registry No 564 male aged 44 years. In January 1924 the patient noticed pain in the right humerus. He was treated with ultraviolet light. In May 1924 he fractured his right humerus while throwing a baseball. In August 1924 the patient noticed a tumor of the lower end of the humerus but no pain. On October 2, 1924 an x ray examination showed a destructive tumor of the lower third of the humerus with a small amount of new bone formation and a pathological fracture. The growth extended nearly to the head of the bone and what appeared to be a similar process was seen in the head of the ulna. On October 9, 1924 a shoulder girdle amputation was done. This tumor has been variously diagnosed as medullary sarcoma and osteolytic osteogenic sarcoma (1924), benign giant cell tumor and osteogenic sarcoma (1930) and reticulum cell sarcoma (1934). In October 1931 a tumor appeared in the amputation scar. This was excised and given x ray therapy. The patient was alive and well January 1, 1938.

Registry No 547 male aged 14 years. In May 1922 he had some pain in the lower right arm. In

ment produces waves of this length. The sensitivity of the negative emulsion therefore limits the possibilities of infra-red photography to some extent. According to the same authors 21 per cent of the total incident energy is reflected by the skin surface, 66 per cent penetrates the stratum corneum and 50 per cent penetrates to the subcutaneous tissue. Waves of 1200 micromicrons undergo complete extinction in 3 millimeters of dead tissue and in the opinion of these authors would undergo more rapid extinction in living tissue due to the effect of the blood. The indistinct or hazy appearance of the veins is due to the scattering of the waves in the tissues. This is similar to the scattering of visible light, especially in the violet and blue region, caused by atmospheric haze. For this reason fine detail cannot be expected of structures as deep as $\frac{1}{2}$ millimeter. It is unlikely, according to Hardy and Muschenheim, that photography of structures deeper than 2 millimeters is possible by infra-red waves, even if the sensitivity of the plates is increased to include waves of 1200 micromicrons, due to the complete extinction of these waves at a depth of little more than 2 millimeters of tissue.

The veins appear in the pictures because there is less reflection of infra-red waves from the areas traversed by the veins than there is from the tissue between the veins. In other words, the veins absorb more of the waves than does the tissue lying between them.

METHOD

The subjects for this study included pregnant women from the prenatal clinic of the Boston Lying-in Hospital, normal non-pregnant women, women from the sterility clinic of the Free Hospital for Women in Brookline, Massachusetts, and 1 patient from the Free Hospital for Women with a large fibroid uterus. The pregnant subjects were photographed at intervals of 2 to 8 weeks throughout pregnancy, the last antepartum pictures being taken as near term as possible. Postpartum pictures were taken when the patients were allowed up, usually from the tenth to the fourteenth day, but in some cases at the eighteenth to the twenty-fourth day. Patients were also photographed at the post-

partum clinic visit at about 6 weeks, and again several months later after the cessation of lactation. The normal non-pregnant women were photographed both during and between menstrual periods. The patients from the sterility clinic were photographed several times, in order to have control observations should any of them become pregnant. One of these patients did conceive as did 1 of the other group of non-pregnant women. The patient with the large abdominal tumor was photographed both before and after operation.

There were 35 pregnant women in the series, of whom 20 were primigravidae and 15 multigravidae. There was a total of 14 non-pregnant women. Six of the primigravidae and 4 of the multigravidae had organic heart disease. Of the patients with heart disease, 1 had a patent ductus arteriosus and 1 had coarctation of the aorta. The others all had rheumatic heart disease with mitral stenosis and insufficiency. Three of the primigravidae and 1 of the multigravidae developed toxemia. One woman was followed throughout her first and second pregnancies, 2 pictures being obtained between the 2 pregnancies. There were 2 cases of twins, both of these mothers developed toxemia. Three of the women were photographed before as well as during and after pregnancy. There were an albino and two negroes in the series. Several of the subjects were also being used for other studies of the circulation in pregnancy (8). These studies included serial determinations of blood volume, venous pressure, circulation time, red blood cell count, hemoglobin, hematocrit, and vital capacity. Several of the non-pregnant subjects were photographed at various phases of the menstrual cycle. In the case of the patient with the large fibroid the abdomen was enlarged to the size of a 6 months' pregnancy.

The regions photographed were the trunk anteriorly and posteriorly and, in a few cases, laterally, and the lower extremities anteriorly and posteriorly. An occasional ordinary panchromatic picture was taken for comparison. A few pictures were taken with the subject lying in bed immediately after delivery, but as it was impossible to obtain the same perspective it is difficult, if not impossible, to

A STUDY OF THE SUPERFICIAL VENOUS PATTERN IN PREGNANT AND NON-PREGNANT WOMEN BY INFRA-RED PHOTOGRAPHY

WILLIAM A GORMAN, M D, Duluth Minnesota

ALBERT HIRSHFIMER M D Dayton Ohio

THIS is one of a group of studies of various aspects of the circulation in pregnancy carried out at the Boston Lying in Hospital under the Department of Obstetrics of Harvard Medical School. Our aim was to demonstrate visually, if possible, any changes occurring in the superficial venous pattern before, during, and following pregnancy, and to attempt to correlate these changes with other facts pertaining to the circulation in pregnancy. For comparison some observations were made on non pregnant women.

Infra red photography of the veins has been done for several years. Masopust (6, 7) has published some observations on the superficial venous pattern in pregnancy with photographs comparing the veins of a primipara and a multipara. He suggests that there are differences peculiar to primiparity or multiparity. He also states that 'the gradual changes in the breasts indicate that a gradual preparation for lactation is taking place which reaches its maximum directly after delivery when the mammary glands are actively functioning. Our conclusion on the first point is directly opposed to his. In addition, we do not feel that such an explanation of the breast venous changes is complete.

Infra red photography is fundamentally the same as ordinary photography but a different region of the spectrum is used. This has been made possible by the development of negative material sensitive to wave lengths in the near infra red, or from about 700 micromicrons to 1100 micromicrons, with maximum sensitivity at about 800 micromicrons. Plates or films which are sensitive to infra red waves

are also sensitive to visible light and ultra violet waves and it is necessary to exclude these waves so that exposure may be made only to infra red rays. Since the type of plate used for most of this study was insensitive to visible red this was most conveniently done by placing over the lens of the camera a filter which allowed only red and infra red rays to pass. Any sort of camera may be used for infra red photography for which infra red sensitive films or plates are obtainable. A camera which is equipped with a ground glass focusing screen is the most convenient type.

The camera used for this study was a Graflex, series D with a Zeiss tessar f 4.5 lens, using either plates or cut film, size $3\frac{1}{4}$ by $4\frac{1}{4}$ inches. The lights were two 500 watt tungsten projection bulbs in reflectors. First man infra red sensitive plates type 1R were used for most of the work, but for the latter part a new type of plate called simply Eastman infra red sensitive plate was used. A Wratten filter No. 25 was used with the type 1R plate. The new type of plate, however, is also sensitive to visible red rays and since the No. 25 filter transmits these a Wratten No. 87 filter, which is opaque to all wave lengths of visible light but transmits infra red rays freely, was used instead. The new infra red plate was slightly faster and somewhat less 'contrasty' than the type 1R plate and required the use of printing paper of one grade higher contrast. This made no practical difference.

The range of sensitivity of infra red sensitive plates extends to 1100 micromicrons with maximum sensitivity at 800 micromicrons. According to Hardy and Muschenheim the most penetrating infra red wave length is 1200 micromicrons. A bright tungsten fila

Fig 1 a, left, H R , aged 23 years, white, nulligravida, not pregnant Infra-red photograph taken on third day of menstrual period b, Same subject Not menstruating Infra-red photograph taken 20 days after beginning of last period

It is within the realm of speculative possibility that hormonal or vasomotor changes accompanying pregnancy can effect dilatation

of the veins We have noted, for example during other studies in this clinic that the veins of pregnant women respond to vene-

compare these pictures with those taken in a standing position

In photographing the subject the distance from the camera to the subject was adjusted so that the area to be photographed filled the negative. This distance therefore varied slightly with the size of the subject. The lights were placed 2 feet to each side of the camera and were directed so as to give as flat illumination as possible since the emphasizing of body contours was not desired. Exposures of 3 seconds at $f\ 16$ were made but if the subject was unsteady or could not control her breathing an exposure of $\frac{1}{5}$ second at $f\ 4.5$ was used. For the occasional ordinary photograph made for purposes of comparison Wratten and Wainwright panchromatic plates were used with the same camera and lights. For these the exposure was 2 seconds at $f\ 32$.

OBSERVATIONS

In the study of the finished prints the following observations were made:

No changes occurred in the superficial veins of non pregnant women during the menstrual cycle (Figures 1, a and b).

There was considerable individual variation among both pregnant and non pregnant subjects. It was not possible to tell from an isolated picture whether or not the subject was pregnant since some of the non pregnant subjects showed a more marked venous pattern than did some of the pregnant subjects. Compare Figures 1, 2, and 3 with Figures 4, d, and 6, e.

There were no demonstrable differences between the changes in the venous patterns of normal pregnant women and those of pregnant women with organic heart disease or toxemia.

There is an increase in the prominence of the veins of the breasts early in pregnancy, noticeable at the third week and very definite at the eighth week. At the time of the first noticeable increase in the veins there is also a noticeable increase in the size of the breasts. The increase in prominence of the veins of the breasts progresses to term and is maintained after delivery during lactation. This accompanies the increase in the breast size. After the cessation of lactation with involu-

tion of the breasts, there is a diminution in the prominence of the veins (Figs 4, 5 and 6).

There is an increased prominence of the abdominal venous pattern first noticeable at about the fifth month when there is obvious enlargement of the abdomen. This prominence of the abdominal venous pattern progresses parallel to the enlargement of the abdomen until delivery. There is an abrupt diminution or in some cases complete disappearance of the abdominal pattern after delivery (Figs 4, 5, and 6).

It is not possible to state from the appearance of the veins whether or not the subject is a primigravida or a multigravida. Individual variations among primigravidae or multigravidae are as marked as the variations between primigravidae and multigravidae. Non pregnant women may have more prominent venous patterns than pregnant women. Compare Figures 3 and 6, d.

Definite changes are limited to the venous pattern of the anterior trunk. Slight and inconstant changes or no changes at all were found on the posterior trunk or the anterior and posterior surfaces of the legs. The depth of the superficial veins of the posterior trunk precludes satisfactory pictures of them.

There is a marked dissimilarity of venous pattern among all the subjects photographed. The individual subjects among the illustrations show a wide variety of pattern.

EVALUATION OF STUDY

In the explanation of the changes noted in this study several factors must be considered. From the fact that there is no constant detectable change and in most cases no change at all in the veins of the lower extremities as pregnancy advances it seems unlikely that venous stasis is responsible since one would expect stasis to be most marked in the veins of the legs for while the venous pressure in the upper extremities remains within normal limits during pregnancy (2) the femoral venous pressure has been shown to be definitely increased (1). Probably whether or not the superficial leg veins become distended depends considerably on the competence of their valves. Certainly the increase of varicosities during pregnancy is incontestable.

Fig 5, a K C, aged 26 years, white, primigravida Pregnancy complicated by rheumatic heart disease with mitral stenosis and insufficiency Infra-red photograph taken June 4, 1936, 26 days before delivery by cesarean section, which was done at term b, Same subject Twenty-three days following section Infra-red photograph taken July 23, 1936 c, Same subject Forty-four days following section Still lactating Infra-red photograph taken August 14, 1936 d, Same subject Seven months following section, 4 months following cessation of lactation Infra-red photograph taken January 28, 1937 e, Same subject Panchromatic photograph taken January 28, 1937, for comparison with Figure 5, d

It is a common clinical impression that the veins in general, and particularly in the arms where they are most frequently observed, seem "fuller" during pregnancy, and we cannot disagree despite the failure of this study to provide graphic proof thereof One would expect the venous blood content to increase, since the general circulating blood

volume increases considerably (9) The cross section of a normal vein is an ellipse the long axis of which is parallel to the skin surface (3) Distention, therefore, would tend to produce a more circular cross section, which, while it would reduce the apparent diameter of a vein, would at the same time make the skinward surface more superficial If, in addition,

the circumference of the vein alters in response to anatomical or functional changes in its wall, a third factor may be introduced. A photograph, of course, shows only two dimensional changes in the veins, and actual alterations may be present which remain undetected. The impression one has as he studies

a series of pictures of the same subject showing the progressive increase of prominence of the veins to term is not so much that they appear to grow larger but rather that they seem to become progressively blacker, more obvious, and less obscured by overlying tissue. After delivery and after lactation has ceased they

appear to become again obscured by intervening tissue

We believe that changes in the depth of the superficial veins over the abdomen and breasts play a large part in their photographic prominence during pregnancy and lactation. On the abdomen this is due to stretching of the skin by the protruding uterus, and, similarly, on the breasts by the increased volume of breast tissue. It will be noted that the appearance of prominent veins parallels the enlargement of the uterus and breasts. It appears likely that the large fibroid of the subject shown in Figure 7, a and b, was stretching the abdominal skin sufficiently to bring out the veins in the pre operative picture. It is also probable that the breast and abdominal veins become prominent partly because of a relatively greater blood content than of veins elsewhere in the body. In the case of the breasts this may be attributed both to a functional increase of circulation and to some interference with venous return into the subclavian axillary system due to the effect of the heavier more pendulous breasts, and in the case of the abdominal veins due to increased femoral venous pressure affecting the epigastric system.

An incidental observation made in this study was that the venous pattern of each subject differed from all the rest. It is suggested that this difference could be made the basis of a system of identification which might be a useful addition to such procedures. Alteration of the whole superficial venous pattern by surgery or by the injection of sclerosing substances would be a possible but a dangerous and painful procedure. The pattern of the superficial venous system should

show almost as much variation as is found in the ridges of the fingertips

CONCLUSIONS

1 Pregnancy is accompanied by definite, photographically demonstrable changes in the prominence of the superficial venous pattern of the anterior thorax and abdomen. Similar changes do not occur in the rest of the superficial venous system.

2 An isolated photograph of the veins gives no evidence as to whether or not the subject is pregnant, or as to her parity.

3 Similar changes do not occur as a result of the various phases of the menstrual cycle.

4 The changes in the prominence of the veins are principally due to the stretching and thinning of the overlying tissues. It is probable that an increase in blood content, and, in the case of the breasts, of physiological hyperemia contribute to the effect.

5 The same type of change occurs in pregnant women with organic heart disease or with toxemia as occurs in normal pregnant women.

6 The usefulness of the peripheral venous pattern as an aid to identification is suggested.

STUDIES ON THE GROWTH STIMULATING EFFECT OF POTASSIUM NAPHTHALENE ACETATE AND POTASSIUM INDOLE BUTYRATE

JOSEPH K. NARAT, M.D., and GEORGE CHOBOT, Chicago, Illinois

A SEARCH for growth promoting substances has led horticulturists to the discovery of so called phytohormones or auxins which stimulate growth by elongation of cells and their capacity of moving downward in the plants. Further studies showed that two closely related substances, named "auxin A" and "auxin B," were responsible for these effects. Later a third, entirely different substance, named "hetero-auxin," was found to produce the same effects (7). A substance called bios, indispensable for the development of yeast and discovered by Wildiers, is closely related to the vitamin B complex (13, 21). The discovery that several synthetic crystalline products cause growth responses in plants served as the basis for work in this field by Zimmerman and Wilcoxon (22, 23), they demonstrated the property to stimulate plant growth in not less than 53 chemical compounds. At the same time auxin was recovered from the human urine in crystalline form (8). Its genesis remains unknown although theoretically its production by intestinal bacteria, its origin from ingested vegetable foods, or its synthesis by the animal organism must be taken into consideration.

All these observations suggested studies of the effects of phytohormones on the animal organism, particularly so because growth promoting substances may find their application in the treatment of burns, indolent ulcers, etc. and also because their rôle in the origin of malignant tumors is within the range of possibility.

From the numerous compounds investigated by Zimmerman and Wilcoxon, two were chosen for the present study, viz., the potassium salts of naphthalene acetic and indole butyric acids, for the following reasons. Indole acids

are closely related to tryptophane, i.e., are not strange to the animal organism; indole acetic acid can be recovered from the urine and the observation has been made that certain indole compounds occur in carcinomatous tissue in concentrations twice that of normal tissue (8). The naphthalene compounds spread readily causing systemic responses, whereas lanolin preparations of indole butyric compounds tend to induce a local response (22). Thus by the use of the potassium salts of naphthalene acetic and indole butyric acids, both the local and general effects of phytohormones could be investigated. Salts were used as they are less toxic in high concentrations than the same concentrations of the acids; salts are also more soluble in water than the acids (22).

The present phytopharmacological investigation was confined to the study of the effect of the two above mentioned synthetic chemical substances on mammalian general growth and local stimulation of regeneration of skin defects.

EFFECTS OF POTASSIUM NAPHTHALENE ACETATE AND POTASSIUM INDOLE BUTYRATE ON GENERAL GROWTH

Interest in stimulation of the growth of the mammalian organism is great, as can be evidenced from the multitude of substances and methods used for this purpose, lactoflavin (6), theelin (2), Lu-Jung (11), glucose (10), organic phosphorus compounds (12), spaying (2, 4) may be mentioned as examples.

For each experiment 3 litter mates with approximately the same weight were used. One rat was injected with the potassium salt of naphthalene acetic acid, another with the same salt of indole butyric acid, the third served as control. The experiment was repeated 7 times so that 21 animals were used for this part of the study.

Chart 1. Sample weight chart ——— Control — — — potassium indole butyrate
potassium naphthalene acetate

To make the effect of the chemicals, if any, more noticeable, the rat with the greatest weight was selected as control, with the idea that the treated rats would catch up in weight with the control animal if the injected substance had a growth promoting effect. Only one reference as to dosage could be found in the literature, namely that of Anderson, Shimkin and Leake (1) who determined the acute intraperitoneal toxicity of some plant growth substances for mice and found that 100 milligrams of indole butyric acid and alphanaphthalene acetic acid per kilogram body weight kills half or more of the animals. Preliminary experiments by the writers showed that both compounds have a cumulative effect. 75 per cent of the calculated lethal dose was distributed over 10 successive days; all the animals died 3 to 7 days later. Apparently the compounds are at least as toxic for rats as for mice as the same dose per kilogram body weight proved to be fatal for rats in spite of the fact that not intraperitoneal but subcutaneous injections, with resulting slower absorption rate, were employed. In view of this fact only 25 per cent of the lethal amount was used in the actual experiments, the total amount of 25 milligrams per kilogram body weight was divided into 10 doses, given on 10 successive days. The accompanying sample weight chart

illustrates the results which were approximately the same in each of the 6 groups. The weight of the treated rats never reached the weight of the control animal, the latter gained in course of 30 days 45 grams or 45.91 per cent of the original weight, the rats which received injections of potassium naphthalene acetate gained only 40 grams or 43.47 per cent of the original weight; the corresponding figures for the rats which received injections of potassium indole butyrate were 35 grams or 35.48 per cent. Measurements of the body and tail length did not reveal any marked differences between the treated and untreated animals. Apparently both chemicals under discussion have no appreciable influence on the growth of young rats.

EFFECT OF POTASSIUM NAPHTHALENE ACETATE AND POTASSIUM INDOLE BUTYRATE ON LOCAL GROWTH

The fascinating study of regeneration is of great interest to the surgeon who is concerned chiefly with the reparative processes following traumatic or operative injuries of tissues. Innumerable methods and substances have been recommended for stimulation of granulations among the newest the following may be mentioned: thyroid extract (3, 14), hypertonic wet dressings (19), thioncisol (13), allantoin (5, 17)

Fig 1 Photograph showing the appearance of symmetrical burns immediately after their production

Fig 3 Appearance of burns 18 days after their production Left side treated with petrolatum, right with potassium indole butyrate

urea (18), sulphydryl group (16) and cod liver oil (9)

The experiments reported here were confined to the effect of potassium naphthalene acetate and potassium indole butyrate on the healing of artificially produced skin defects. First, an attempt was made to excise approximately equally large portions of the skin from the dorsal region of rats on either side, one to serve as control and the other to be treated with local applications of the chemicals, it was discovered, however, that it is practically impossible to create with a scalpel or scissors skin defects of equal size

A rectangular branding iron, 18 millimeters in diameter, was found to serve the purpose best, the duration of the application of the hot iron and the pressure applied to it were gauged so as to produce a burn of the entire thickness of the skin. The first application of the 5 per cent ointment of the compounds in a lanolin vaseline base was made approximately 15 minutes after the production of a burn, the following applications were repeated at daily intervals for 7 days. The accompanying photographs show that the treated areas were healed 16 days after the production of burns, whereas 22 to 28 days were required for epithelization of the untreated burns. In other words, the

application of the ointments containing salts of indole butyric and naphthalene acetic acids

BONE SARCOMA

Factors Influencing the Prognosis

CHANNING C. SIMMONS, M.D., F A C S, Boston, Massachusetts

THE following is a report of the results of treatment of the 47 patients with primary malignant tumors of the long bones, excluding plasma cell myeloma, admitted to the surgical wards of the Massachusetts General Hospital during the 13 year period 1920 to 1932.

This series is a representative group of tumors of this character seen in a general hospital but the results of treatment should not be compared to those obtained in a children's hospital to which patients over 12 years of age are not admitted. It was felt that the figures as to the curability of bone sarcoma obtained by an analysis of the cases in the Registry of Bone Sarcoma of the American College of Surgeons would give an erroneous impression, for physicians are prone to report or register the successful cases and not the failures.

The cases here reported, with the exception of Case 48, have been registered with the Registry of Bone Sarcoma. The specimens from the cases of patients living 5 years have recently been reviewed by Drs S B Wolbach and Tracy B Mallory, pathologists, and by Dr E A Codman in order to bring the pathological classification more closely in line with our present day knowledge.

No case is considered a cure unless the patient is living without evidence of disease 5 or more years since treatment. Three patients died of sarcoma more than 5 years from the date of operation (in 1 instance 12 years), and these cases are considered as failures.

The patients were all seen before it became the custom to study the blood chemistry. At present calcium, phosphorus, phosphatase, and serum protein determinations are made as a routine in all cases. Roentgenograms of the chest were taken before operation to exclude metastases as far as possible.

All of the 47 patients with sarcoma admitted to the hospital during the 13 year period have been followed to date (Table I).

TABLE I — PRIMARY MALIGNANT BONE TUMORS

	Cases
Surgical treatment.	37
X-ray treatment	6
No treatment	4
Total cases (all types)	47

Excluding the 4 cases who refused treatment, the 43 remaining may be divided into three main groups (Table II).

TABLE II — SARCOMA, PATHOLOGICAL TYPES

	Cases
Osteogenic sarcoma	33
Ewing's sarcoma	8
Reticulum cell sarcoma	2

In reviewing the cases, the percentage of 5 year cures was found to be much larger than that usually reported, although it is unlikely that the surgical and radiation treatment is different in this institution from that obtaining in any comparable general hospital.

OSTEOGENIC SARCOMA

The largest group is that of the osteogenic sarcoma. Three died, without recurrence, of intercurrent disease within 5 years from the date of treatment and are excluded in determining the end-results. One of these died of acute appendicitis 2½ years after operation, 1 following an operation for acute cholecystitis 3½ years after operation, and 1 of a cardiac condition 2 years after operation. Excluding these 3 cases the results of treatment are shown in Table III.

TABLE III — OSTEOGENIC SARCOMA — RESULTS

	Cases	Cures	Per cent
Surgical treatment	28	11	39
X-ray treatment	2	0	0

shortened the healing period by about 35 per cent as compared with the time required in control lesions. Potassium indole butyrate accelerated the regeneration of the skin in a higher degree than potassium naphthalene acetate. The scab remained on the burns an equal time after the application of either salt, but when the scab was slightly lifted 8, 10, or 12 days after the production of the burn it could be seen that larger areas were covered with new epithelium when the first mentioned compound was used (Figs 2 and 3).

For the sake of comparison in 6 rats the burns on the left side were treated with potassium naphthalene acetate and the burns on the right side of the same animals with a brilliant green jelly, the healing rate was approximately identical on both sides. In a similar experiment in which potassium indole butyrate was used, the healing time averaged 2 days less as compared with brilliant green.

In another series of experiments the right burns were treated with potassium naphthalene acetate or potassium indole butyrate respectively, while a 10 per cent tannic acid spray was applied to the left burns on 3 successive days (Fig 4). The healing period was practically identical on the right side, no matter which compound was used. All the burns on the right side healed as an average in 18.3 days while 24.7 days were required for the healing of the burns treated with tannic acid. The observation was made that scabs formed over the burned areas treated with the potassium salts of either of the two chemicals studied were softer, more flexible, and not so firmly adherent to the subjacent tissues as those covering burns treated with tannic acid.

SUMMARY AND CONCLUSIONS

1 Under conditions used in this experiment potassium salts of naphthalene acetic acid and indole butyric acid had no effect on the general growth of young rats.

2 A marked stimulating effect of these two chemicals on the regeneration of burned skin

was observed. The healing rate was more accelerated by the salt of the indole butyric acid than it was by the salt of the naphthalene acetic acid.

3 The local growth promoting effect of both chemicals was comparable to the effect of brilliant green jelly.

4 The local healing effect of both chemicals was much more pronounced than the effect of tannic acid.

5 More extensive investigations, including other animals in addition to rats, are desirable to appraise the therapeutic value of potassium naphthalene acetate and potassium indole butyrate in the treatment of burns and other skin defects.

The writers wish to express their sincere gratitude to Dr George Wakerlin for his great help in carrying out this work.

rarely extends to the joint cartilage The longitudinal diameter of the defect is also usually greater than the transverse, which is not the case in giant cell tumor Microscopically these tumors are composed of spindle cells with foreign body giant cells about the periphery where bone is being destroyed The

TABLE IV — OSTEOGENIC SARCOMA —
RESULTS OF SURGICAL TREATMENT

	Cases	Cures	Per cent
Fibrous type	5	5	100
Chondral type	7	5	70
Anaplastic type	16	1	5.5

Fibrous type There were 7 cases in this group Five were treated by amputation and all 5 are living The greater portion of the tumors was composed of relatively adult fibrous tissue Two were treated by radiation and died of disease, one 6 and one 7 years after beginning treatment (Figs 1 and 2) These 2 were cases of central sarcoma of the fibrous type erroneously diagnosed by x-ray as giant cell tumors At first glance, the roentgenogram in the central type somewhat suggests a giant cell tumor. The growth is centrally placed, is bone destructive, and causes slight distention of the cortex, but

Fig 5 Osteogenic sarcoma tibia chondral type Photomicrograph of specimen, Case 44 (Figs 3 and 4)

Fig. 1 Case 24 Osteogenic sarcoma fibrous type (Fig. 2) Female aged 21 years Symptoms for 1 month Amputation Well 6 years The roentgenogram is atypical

By surgical treatment amputation is meant, the entire affected bone being removed when this was possible. In tumors of the humerus disarticulation at the shoulder joint was performed rather than shoulder girdle amputation. In tumors of the lower end of the femur amputation was performed at the level of the lesser trochanter, but, if the shaft appeared to be involved, hip joint amputation was done. There was no operative mortality in this series.

Osteogenic sarcoma may be defined as a tumor originating from the embryonic fibroblast, which, under normal conditions, would differentiate into normal bone. The embryonic fibroblast may form fibrous tissue, cartilage or osteoid tissue.

If we accept the idea just mentioned it is easy to account for the various forms of tissue, i.e., bone, osteoid tissue, cartilage, and adult fibrous tissue, found in the usual bone sarcoma. It was felt that the high percentage of cures obtained in this series might depend on a large proportion of the cases showing a high degree of differentiation of the cells, that is, if

Fig. 2 Photomicrograph of specimen Case 24. The specimen is composed chiefly of cellular fibrous tissue but shows areas of osteoid tissue, cartilage and bone.

the major portion of the tumor was composed of adult tissue, cartilage, or bone, the tumor would prove to be less malignant than it would if composed of undifferentiated fibroblasts.

The cases of osteogenic sarcoma were therefore divided into three main groups which have been termed fibrous, chondral, and anaplastic. The tumors in all of the cases were histologically malignant, and in certain portions tumor giant cells and many cells undergoing mitosis could be found, but in the fibrous and chondral groups adult fibrous tissue or cartilage predominated. In the anaplastic group the greater portion of the tumor was composed of highly malignant cells.

Certain of the pathologists previously mentioned state that some of the cases I have placed in the fibrous and chondral groups probably should be placed in the anaplastic group, but the opinions as to which ones should be so placed varied. If the cases in which the patients were treated surgically are divided into the three types above mentioned, namely, fibrous, chondral and anaplastic, the results of treatment are as shown in Table IV.

somewhat older than the patients in the anaplastic group. It must be borne in mind, however, that children under 10 are not often admitted to this hospital. Trauma was mentioned as an etiological factor in 5 of the 7 cases.

It is impossible to distinguish the fibrous type clinically or by x-ray from the other more malignant forms of osteogenic sarcoma; and as far as can be determined, the only reason why the results of treatment were satisfactory is the fact that the major part of the tumor was composed of highly differentiated cells.

Chondral type There are 9 cases in this group, 7 of which are suitable for end-result study (Figs 3, 4, and 5). Five are living and well, while 2 are dead of a recurrence of the disease. Pathological examination of all these tumors showed cartilage to be the predominating tissue, but portions of the tumors appeared to be highly malignant. It is often difficult histologically to distinguish between a benign chondroma and a sarcoma.

Clinically, the striking feature of this group was that 5 of the 9 patients were over 50 years of age when the tumor was first noticed.

Fig 10 Case 66 Reticulum cell sarcoma humerus (Fig 9)

Fig 9 Case 66 Reticulum cell sarcoma lower end of the humerus. Male, aged 42 years. Amputation. Local recurrence removed 7 years later. Well 6 years after second operation (Fig 10).

One of these patients probably had Paget's disease of the bones as well, but the history suggests malignant changes occurring in a previously benign tumor. This is known to have occurred in 2 instances. In Case 49, a cure, the patient had a benign chondroma removed three times. Some time after the third removal it recurred, grew rapidly, and at operation proved to be sarcoma. Comparing the specimen removed at the last operation with those removed previously, the character of the growth had changed. In another case, a chondroma had been removed 13 years previously, and the patient considered himself well during the interval. The growth then recurred and amputation was performed, but the patient died a year later of lung metastases.

The roentgenograms in these cases showed in most instances nothing characteristic that

presence of a few foreign body giant cells may lead to the erroneous diagnosis of giant cell tumor unless this is borne in mind. That the central fibrous type of osteogenic sarcoma is of low malignancy or radiosensitive is suggested by the fact that the 2 patients treated by x ray lived for several years before showing evidence of lung metastases. One of the cured cases in which amputation was done was of this character. I have seen another similar case, not in the series, in which amputation was performed, and the patient is living and well over 5 years after operation.

Five of the 7 were of less than 6 months' duration from the first symptom to the initiation of treatment, one 9 months, and one 12 months. In one of the cured cases the patient had been subjected to curettage under the

Fig 8 Case 2 Osteogenic sarcoma Anaplastic type (Figs 6 and 7)

but no evidence of metastases. When metastases occur they are usually seen in the lymph nodes or soft parts rather than in the lungs, although the latter may be involved. When a tumor of this type is primary in the lymph nodes it runs a relatively short course, 2 to 3 years, to a fatal termination, but when primary in the bone it appears to be relatively non-malignant, although in the light of the history of these 2 cases there is apparently the possibility of a late recurrence. This might be considered another manifestation of the disease and not a true recurrence. In the 2 cases in this series the tumors were situated in the humerus, 1 in a 12 year old girl and 1 in a 42 year old man. Shoulder joint amputation was performed in both instances. The girl died 12 years later with a tumor of the femur. Unfortunately no history, x-ray, or biopsy report of this second tumor is available. The man had a massive local recurrence in the soft parts about the shoulder 7 years after amputation. This was excised and the operation followed by x-ray therapy. The patient is well today, 7 years after removal of the local recurrence and 14 years after the amputation.

These tumors are radiosensitive, but Parker and Jackson found that with the exception of the case here reported, all but 1 case in which amputation was performed were living over 5 years, while of those treated only by radiation, all were dead, or, if living, showed definite evidence of disease.

It would appear that Parker and Jackson have been able to distinguish a type of primary bone tumor, not previously recognized, which pursues a definite clinical course not in any way resembling that of an osteogenic sarcoma. It is probable that certain of the reported cases of cures of both Ewing's tumor and osteogenic sarcoma were unrecognized tumors of this character.

EVALUATION OF STUDY

From this analysis it would appear that the prognosis in a series of cases of malignant bone tumors taken consecutively as they are admitted to a general hospital, is far from hopeless when they are treated by radical surgery. Although all the cases reported were considered malignant, the time at which

metastases occurred obviously varied. In reviewing the specimens, the tumors in which relatively adult tissue, such as fibrous tissue and cartilage, predominated did not form metastases for some time after the tumor was noted clinically, and the patients were therefore cured by complete removal of the growth.

The time element, that is the duration of the tumor before treatment, undoubtedly has a bearing on the result in a given case, although if these cases are considered as a group, this is not so. The prognosis appeared to be worse in the cases of short duration, but it was found that the duration in the majority of the tumors of low malignancy, in which cures were obtained, was appreciably longer. This same relation between duration of disease and prognosis has been found to obtain in studying groups of cases of cancer of the breast. There is only 1 case of short duration in this series, a 7 year cure, and this occurred in the family of a physician. There had been symptoms for about 3 weeks, although the roentgenogram suggested a tumor of longer duration, and operation was performed within 24 hours from the time the diagnosis was suspected.¹

It is difficult to obtain the consent of the patient or the parents to amputate for a small tumor, and they will grasp at any form of treatment first that does not sacrifice the extremity.

The value of pre-operative radiation treatment is problematical. It was not employed in any case in this series, for the time element was considered more important. Radiation undoubtedly affects the cells profoundly but apparently does not destroy the tumor. There is no instance of cure by radiation alone of a proved case of osteogenic sarcoma in the Registry.

The surgical procedure adopted whenever possible was a biopsy performed with a tourniquet on the limb, frozen section examination of the tissue removed, and immediate amputation if the tumor was reported to be sarcoma. A suction biopsy done some

¹ Since this paper was submitted for publication Case 24 (Registry of Bone Sarcoma No. 1254) presented evidence of two metastases in the lung, 7 years after operation. These were successfully removed by lobectomy. The histology of the metastases was the same as that of the original tumor.

Fig 11 Registry of Bone Sarcoma No 1992 This shows the characteristic appearance of one form of reticulum cell sarcoma and is to be compared with Figure 9 The case is not included in this series

would serve to distinguish this type from other forms of sarcoma Three of the tumors were in the upper end of the tibia, 2 in the metatarsals, and 1 each in the radius, humerus, femur, and scapula Trauma was mentioned as an etiological factor in the history in 4 of the 9 cases In no case in this group was the duration of the disease from the first symptom to operation less than 4 months, and in 5 instances it was over a year In other words, the tumors were of slow growth and metastasized late in the course of the disease

Anaplastic type There were 21 cases in this group Four refused treatment and 1 died of intercurrent disease (operative death following cholecystectomy) and have been excluded in determining the end results of treatment Of the 16 remaining only 1 is living (5.5 per cent cures) (Figs 6 7 and 8) In all these cases the major portion of the tumor was composed of anaplastic cells although small areas of adult cartilage bone, and fibrous tissue could be found Twelve of the patients were under 22 years of age, and 4 cases were over 60, but in the latter group the disease was secondary to Paget's disease

of the bone Twelve of the 21 tumors arose about the knee joint

Excluding the cases with Paget's disease, in 10 of the 16 patients, the symptoms were of less than 3 months' duration when the patients sought treatment, while in 2 cases, 1 a cure, symptoms had been present 4 months The average duration of the disease from first symptom to operation was considerably less than in the two forms previously discussed, yet the tumors had obviously formed metastases when first seen

The roentgenograms were characteristic of a malignant bone tumor and all showed bone destruction and new bone formation in varying amounts There was no way clinically, however, to differentiate this form from that in which cartilage or adult fibrous tissue predominated

EWING'S SARCOMA

There are 8 cases of Ewing's sarcoma in the series All died of disease Four were treated by amputation and 4 by x ray, the latter cases with marked temporary improvement

RETICULUM CELL SARCOMA

There are 2 cases of this type of tumor in the series, but I have seen others and there are several in the Registry collection Most of the cases in the Registry have been placed under the heading "malignant disease of bone, unclassified" Recently Parker and Jackson have reviewed these cases, with others of their own and believe the growths are identical with the so called reticulum cell sarcoma of the soft parts Their paper appears elsewhere in this issue These tumors run a different course from that of osteogenic sarcoma In the early stage of the disease the symptom common to all malignant bone tumors is present that is, pain unrelieved by rest Later a tumor is noticed which grows rapidly, and although it may attain considerable size the general condition of the patient remains excellent (Figs 9 and 10) In the roentgenogram the tumors originate in the medulla, which in the early stages has a mottled appearance (Fig 11) and may be confused with osteomyelitis or Ewing's sarcoma Later there is bone destruction and a bulky tumor

Case 47, Registry 1217. Female, aged 68 years. Scapula Trauma, 11 months, pain, 6 months, tumor, 3 months, excision of scapula Pathology. osteogenic sarcoma chondral type Local recurrence in 11 months Excised Well 5 years after second operation

Case 48, not registered Female, aged 59 years Lower end of radius Trauma, 5 years, followed by pain and swelling Three minor operations performed with no improvement Amputation Pathology osteogenic sarcoma chondral type Well 5 years A probable example of a chondroma assuming malignant qualities

Case 49, Registry 2133 Male, aged 15 years Upper end of tibia Tumor, 5 years, no trauma, removed 3 times by wide local excision but recurred Pathology chondral type Well 5 years A typical example of a benign chondroma changing its character and becoming malignant

Case 65, Registry 63. Female, aged 12 years Upper end of humerus Tumor, 3 months, curetted for osteomyelitis Amputation Pathology probable reticulum cell sarcoma Said to have died 12 years later of a tumor of the lower end of the femur Unfortunately we do not know the character of the tumor of the femur It was probably another manifestation of the disease and should not be considered as a true recurrence

Case 66, Registry 564 Male, aged 44 years Lower end of humerus Pain, 10 months, fracture, 5 months, tumor, 2 months Amputation Pathology reticulum cell sarcoma Recurrence in soft parts about shoulder 7 years later Excised Radiation Pathology, same Well 6 years after second operation

I do not consider this man necessarily cured, for I think these tumors belong in the lymphoma group and later manifestations of the disease may develop

time prior to operation might disseminate the disease. Two of the cured cases of osteogenic sarcoma, however (Cases 7 and 8) had been curretted some time before amputation under the erroneous diagnosis of osteomyelitis, and one case of reticulum cell sarcoma (Case 65) had also been explored.

There is no way by which the various types of osteogenic sarcoma may be distinguished clinically with any degree of accuracy, although occasionally the character may be suspected. In individuals over 50 the tumor is usually secondary to Paget's disease of the bone (4 cases in this series) or of the chondral type (5 of 9 cases). In the chondral type it usually represents malignant changes occurring in a small pre-existing island of cartilage.

The 8 cases of Ewing's sarcoma are all dead. My experience with this tumor is limited to 26 cases, some patients being treated by radiation and some by operation but all are dead. There are a few 5 year cures, however, in the Registry collection.

The most interesting group, although small is that of the primary reticulum cell sarcoma of bone. The nature of this disease shows a destructive process in the medulla in the epiphyseal end of the diaphysis, often multiple small areas with no new bone formation. The picture is suggestive of other forms of malignant lymphoma of bone. Later there is a bulky tumor destroying the bone, but the patient remains in excellent physical condition. These tumors are radiosensitive but from the data at hand the results are more satisfactory following radical surgery than following radiation treatment.

CONCLUSIONS

1. The prognosis in a series of consecutive cases of osteogenic sarcoma is not as poor as is generally believed if the tumors are removed by radical surgery.

2. Of 28 cases of osteogenic sarcoma in which amputation was done, 11 patients 39 per cent, are living without disease 5 or more years after operation.

3. The prognosis depends more on the amount of differentiation of the cells comprising the major portion of the tumor than on any one other factor.

4. If the tumor is composed in large part of adult fibrous tissue or cartilage, the prognosis is better than if the cells show marked anaplasia.

5. In 5 cases in which fibrous tissue predominated, patients were treated by amputation. All are well (100 per cent).

6. Of 7 cases in which amputation was done and in which cartilage was the predominating tissue, 5 patients are well, 70 per cent.

7. Of 16 cases in which amputation was done and which may be placed in an anaplastic group, 1 is well (5.5 per cent).

8. Two cases of reticulum cell sarcoma in which amputation was done are reported. One patient is well 14 years later, and 1 died 12 years later of a tumor of another bone, the character of which was not determined.

9. Of 8 cases of Ewing's sarcoma, 4 patients were treated surgically and 4 by radiation. All patients died of the disease.

ABSTRACTS OF HISTORIES—CURED CASES

Case 2 Registry 407. Male aged 31 years. Lower end femur. Pain, 1 year. Trauma 9 months. Tumor 3 months. Amputation. Pathology: sarcoma fibrous type. Low malignancy. Well 10 years.

Case 5, Registry 214. Male aged 38 years. Lower end femur. Trauma 16 months, tumor 4 months. Amputation. Pathology: sarcoma fibrous type. Well 6 years.

Case 7 Registry 312. Male aged 18 years. Lower end femur. Trauma 4 months. Curretted for osteomyelitis 3 months. Amputation. Pathology: sarcoma fibrous type. Well 14 years.

Case 8 Registry 344. Male aged 17 years. Upper end tibia. Trauma 1 year. Pain 4 months. Tumor 3 months. Curretted for osteomyelitis. Amputation. Pathology: highly malignant sarcoma. Well 8 years.

Case 23 Registry 945. Male aged 16 years. Tumor upper end of tibia 10 months. No trauma. Amputation. Pathology: osteogenic sarcoma chondral type. Well 7 years.

Case 24 Registry 1254¹. Female aged 21 years. Shaft humerus. No trauma. Pain 1 month. Amputation. Pathology: sarcoma fibrous with cartilage. Low malignancy. Well 6½ years.

Case 28 Registry 1572. Female aged 16 years. Lower end of femur. Probable trauma. Tumor 4 months. Amputation. Pathology: sarcoma central fibrous type. Low malignancy. Well 5½ years.

Case 44 Registry 945. Male, aged 18 years. Upper end of tibia. Trauma 9 months. Tumor 3 months. Amputation. Pathology: osteogenic sarcoma chondral type. Well 6 years.

CLINICAL SURGERY

FROM THE JAMES BUCHANAN BRADY UROLOGICAL INSTITUTE

A NEW RADICAL OPERATION FOR CARCINOMA OF THE BULBOUS URETHRA

A New Use for the Penis

HUGH H. YOUNG, M.D., F.A.C.S., Baltimore, Maryland

THE case of carcinoma of the bulbous urethra which is described here seems worthy of report, inasmuch as it furnishes a completely radical procedure without mutilation or stricture. In this patient, after an extensive block dissection, a great urethral hiatus was eliminated by telescoping the penis backward and suturing it to the triangular ligament.

CASE REPORT

BUI 26189, J. B. D., a man, aged 59 years, was admitted September 21, 1937, complaining of a gradually increasing lump about the urethra in the region of the scrotum and perineum of 2 months' duration. The family history was negative, and the past history was non-contributory. He had had acute gonorrhea 40 years ago. This disappeared under local treatment, but subsequently he had prostatitis, for which he was treated 20 years ago. His physician reported that he had not had a prostatitis recently and that his Wassermann test was negative. His sexual powers were normal, and several months before admission he was having intercourse about every 10 days. Three years ago, at the age of 56, the patient noticed some hesitancy at the beginning of urination, and a decrease in size of stream. A diagnosis of urethral stricture was made, and he was treated by the passage of sounds, beginning with No. 18 F. These dilatations were continued at intervals of about 5 weeks for 3 years, a No. 29 F. sound being frequently introduced. These treatments kept the urethra dilated so that urination was quite satisfactory until about 2 months ago, when, following the passage of a No. 29 F. sound, he noticed marked discomfort in the urethra. On palpation the patient then felt a pea-sized lump along the urethra in the perineum. After that the lump gradually increased in size until it reached about an inch or so in length. He was treated by diathermy with no reduction in the size of the indurated area. After the onset of the induration there was a complete cessation of erections and libido. Recently it had been found impossible to pass a sound of the usual size, and difficulty in voiding urine had returned.

The patient was referred by Dr. William R. Barron, Columbia, South Carolina, who had found a markedly indurated area around the urethra which he considered suspicious. The patient was voiding urine without much difficulty or frequency and was enjoying excellent health, but had had no libido, erections or coitus for several

months. He complained of a hard mass around the urethra, back of the scrotum, which gave him no pain. There was no history of hematuria or urethral discharge.

On examination the penis and scrotum appeared normal (Fig. 8). Palpation along the urethra revealed a markedly indurated area around the urethra beginning at the penoscrotal junction and extending back for a distance of about 5 centimeters. The mass was hard, slightly irregular, somewhat fixed, about 2.5 centimeters wide, and apparently entirely within Colles' and Buck's fasciæ. The skin and subcutaneous tissues and the scrotum and its contents were not fixed to it. The posterior part of the bulb and crura of the penis were negative. The mass, about 5 centimeters in length, was not adherent to, and apparently did not involve, the symphysis pubis or the ischiopubic rami. Its location is shown in the clinical sketch (Fig. 1 and also in Fig. 2, 1). No enlarged glands were found along the penis, in the perineum, or in the groin on either side. The testicles, epididymides, vasa, and veins were negative. On rectal examination the anal sphincter and rectum were found to be negative. The prostate was about normal in size, shape, and consistence. The seminal vesicles were slightly indurated. The membranous urethra was soft and normal in size. With the finger in the rectum and the thumb on the perineum one found slight enlargement and a little thickening of the bulb at or near its posterior limit. A short distance below this point an indurated mass was felt which surrounded the urethra and rapidly became wider and thicker, apparently involving much of the bulb and urethra. The mass was movable, not adherent to the lateral structures of the perineum, and stopped abruptly near the penoscrotal junction. Bougies à boule and catheters introduced in the urethra met with an impassable obstruction within the scrotal portion of the urethra where the hard mass was palpable. It was so dense that no effort was made to pass filiforms, followers, or sounds, as the diagnosis of carcinoma seemed evident.

The urine was clear, acid, specific gravity, 1.020, no albumin, sugar or white blood cells were present, and only 1 or 2 red blood cells per high powered field. No infection was seen. The phthalein test showed an appearance time of 8 minutes, and half hourly outputs of 56, 20, 12, and 4 per cent, two hour total 92 per cent. The blood urea was 28 milligrams per cent; hemoglobin 100, leucocytes, 7,350. The diagnosis was coronary arteriosclerosis, heart disease, a subsiding upper respiratory infection, and malignant tumor of the urethra. As a portion of the bulb and urethra back of the tumor were apparently free from invasion, the possibility of a radical operation seemed excellent.

tance of about 9 centimeters between the stump of the urethra behind and the section of the urethra and cavernous bodies anteriorly (Fig 5, 3) The anterior portion had retracted into the depths of the scrotal wound. By grasping the fasciæ with forceps, we found it possible to draw the remaining cavernous bodies of the penis backward without difficulty until they could be made to touch the cut end of the urethra posteriorly (Fig 6, 1) In so doing the penis was telescoped within the penoscrotal pouch until only the glans penis was visible (Fig 6, 1 and 2) Anastomosis of the two cut ends of the urethra was then made with fine 10 day catgut, a continuous stitch being employed (Fig. 6) A catheter was introduced just before closure of the line of urethral sutures The cavernous tissues and surrounding fasciæ were then drawn together with interrupted sutures of plain

catgut (Fig. 7, 1) some of which were placed in the stumps of the crura on each side, some into the deep structures of the triangular ligament The anastomosis was easily carried out without tension and seemed entirely successful It was surprising how easily the penis had been drawn back to be sutured to the triangular ligament (Fig. 7, 2 and 3). The subcutaneous tissues were then drawn together in the median line with interrupted plain catgut sutures, and the skin was closed with silver wire sutures Examination showed the glans and about 1 centimeter of the shaft of the penis protruding from a pouch at the penoscrotal juncture (Figs 7, 3 and 8) The contrast between the length of the penis before and after operation is shown in Figure 8 The scrotal contents appeared normal The catheter, which had been introduced, was fastened in the penis with adhesive, the

Fig. 2 Clinical chart showing location and size of carcinomatous mass. HUI 26189. Arrow indicates negative prostate. cross hatched area very hard mass around anterior half of bulbous urethra.

Operation was carried out September 22 (by H H Y), using avertin gas ether anesthesia. A McCarthy urethroscope was introduced before the operation was started and revealed a slight irregularity and marked narrowing of the urethra in the region of the mass, but no ulceration or projecting neoplastic tissue was visible. With the patient in the position for perineal prostatectomy an incision 6 centimeters long was made in the midline of the perineum just behind the scrotum which was pulled forward (Fig 2, 2). Colles fascia covering the bulb of the urethra was isolated on each side to the ischiopubic ramus. It was smooth, but beneath it a markedly indurated mass occupying the anterior two-thirds of the bulb and extending up to the scrotal portion of the penis was found (Fig 2, 3). After exposing Colles fascia, which covered the cavernous bodies, palpation of the mass showed that it was of third degree induration and slightly irregular. There were no areas of softening and nothing suggesting local areas of suppuration or sinuses. It seemed evident that the diagnosis was surely carcinoma but before I began the proposed very radical operation it seemed wise to take a biopsy. An incision was made on the posterior surface of the mass. Colles fascia and the tissue immediately beneath it did

not appear to be involved, but the scalpel soon encountered the markedly indurated tissues which on cut section gave every evidence of being carcinoma. Nevertheless, a wedge shaped piece (Fig 3, 2) was removed and the wound packed while the operator waited for the report on microscopic examination of the stained frozen section. In 10 minutes the diagnosis "carcinoma" was received and we proceeded to carry out a very extensive radical operation (Fig 3, 2) to remove the mass with its surrounding fasciae and a goodly portion of the cavernous bodies anteriorly, and much of the uninvolved bulb behind. The scrotum was retracted well forward and blunt dissection was continued downward outside the fasciae covering the corpora (Colles' and Buck's) until a point about 2 centimeters below the lower margin of the indurated mass was reached. A clamp was then passed around the cavernous bodies and their fasciae, and a transverse incision was made through the corpus spongiosum and corpora cavernosa (Fig 3, 1) thus the scrotal portion of the penis was completely severed. On examination it seemed desirable to remove more of the cavernous bodies and a second incision was made transversely through them at a point about 1 2 centimeters farther down (Fig 3, 1). (In the drawings, Fig 3, 1 and 2 only this incision is shown.) After the cavernous bodies were divided, the fascia covering them was seized with forceps, and by sharp and blunt dissection they were freed from the structures in front. A suspensory ligament was recognized and divided, and the adhesions to the anterior surface of the pubes and ischiopubic rami on each side were divided close to the bony structures (Fig 4, 1 and 2). The dorsal arteries and veins were divided, bled freely and required ligation, both at the upper and lower end of the dissection. When the mass was pulled outward and the dissection carried backward the crura of the corpora cavernosa were encountered on each side, and divided close to the ischiopubic rami (Fig 5, 1). One could then palpate the urethra as it left the bulb and penetrated the triangular ligament. Below it was a portion of the bulb which was free from involvement for several centimeters behind the malignant mass. A clamp was placed beneath the urethra and an incision was then made through the bulb just in front of its posterior limit (Fig 5, 2). This incision was continued through the urethra at a point about 1 centimeter in front of the triangular ligament (Fig 5, 3). The mass with its surrounding fasciae and uninvolved tissue of the bulb behind and the cavernous bodies below was removed. After all hemorrhage had been carefully arrested inspection showed a dis-

Fig 4 1, Colles' fascia has been cut away from ischiopubic ramus on each side. Suspensory ligament has been divided and mass dissected backward, exposing anterior surface of symphysis and ischiopubic ramus. Penis has retracted into scrotum. 2, Continuing deep dissection. BUI 26189

He had no pain, local or remote. He had not lost weight, and was enjoying excellent health. He had had no erections (but these were stated to have been absent 2 months before operation).

The patient looked well and weighed 175 pounds. The penis was normal in width but very short (Fig 9). The glans measured 4 centimeters wide and 3.5 centimeters long. Above this the shaft of the penis could be followed into a pouch beneath the pubic fat for a distance of 3.5 centimeters. In the median line of the perineum was a narrow scar 7 centimeters in length and with very little induration. On palpation much less tissue than usual was found in the region of the bulb. Far forward, in the region of the scrotum, the cavernous bodies felt about normal in size. Passing backward they became gradually smaller down to the point where the anastomosis was made just below the external sphincter. No bulb and no crura were palpable. There was very little cicatrix at the site of anastomosis and elsewhere

the tissues were soft. There was nothing to suggest a recurrence. No enlarged glands were palpable in either the perineum or the groins. On rectal examination the prostate was found to be negative and no glands were palpable. The patient voided about 500 cubic centimeters of clear urine. No sounds or other instruments were passed.

One year after operation the patient was reported to be well.

REPORTED CASES

Primary carcinoma of the male urethra is comparatively rare. In 1923, after reporting 1 case, Kretschmer brought the total number in the literature to 80. In 1931, Lower assembled 112 cases to which he added 3 cases that had come under his personal observation. In 1932, Kirwin, after excluding certain reports, stated that the total number of acceptable cases of carcinoma of the male urethra in the literature was 99. In 1937,

Fig. 3. 1 Section through Colles fascia into indurated mass for biopsy. Incision was closed while waiting for microscopic report (see). After isolation of root of penis and careful avoidance of penetration of Colles and Buck's fascia a clamp was placed around 3 corpora well up in scrotal portion of urethra which was made visible by firm retraction of scrotum. 2 Division of corpora and beginning isolation of posterior part of penis and penneum. BUI 26189.

bladder was washed clean and a drainage apparatus was attached. The operation had not been difficult and was apparently thoroughly radical and satisfactory.

Two specimens were removed at operation, the larger weighing 27 grams and measuring 3.3 by 3.3 by 2.5 centimeters, the smaller which was a transverse section of the three corpora of the penis measured about 1.5 centimeters in thickness. The urethra in the larger specimen measured 3.3 centimeters in length and was surrounded by the tumor. The urethra appeared normal. No nodules or ulceration of the mucosa were visible. Immediately beneath the mucous membrane was found a firm hard nodular mass between the urethra and the corpora measuring 2.5 by 1.3 by 1.3 centimeters. Three sections were taken through the urethra, tumor and corpora for sections.

On microscopic examination of the tissue a squamous cell carcinoma of the urethra was seen. The framework was made up of fairly dense fibrous tissue and scattered throughout this were seen small irregular nests of tumor cells which were characterized by great variation in size, shape and staining characteristics. In the center of many

of these nests were found epithelial cells with varying stages of keratinization. The urethral mucosa was lined with normal transitional cells. Adjacent to it but not involving it was a tumor mass above described. In places the tumor cells were characterized by huge clear cytoplasm and small round pyknic nuclei. One group of these cells was closely packed together without intervening stroma. On the opposite side of the urethra a section of one corpus cavernosum appeared entirely normal.

The catheter was removed from the urethra on the sixth day after operation. Following this the patient voided some urine through the incision but it healed completely in 18 days. There was a marked urethral discharge which soon disappeared. The patient left the hospital one month after operation voiding freely without pain and with excellent control. He had no urethral instrumentation after removal of the indwelling catheter. He was given mandelic acid by mouth because of a urinary tract infection with the *Staphylococcus aureus*. He was advised to continue this on returning home.

On April 21, 1938 the patient returned for observation (7 months after operation). He had had no instrumentation. He voided urine freely in good stream at intervals of 6 hours, night and day and often did not arise at night.

Fig 6 It was found to be easy to draw penis backward so as completely to cover defect and anastomose two ends of urethra and corpora BUI 26189

noma in the intestinal tract, Deetz in the biliary tract, Hallé in the renal pelvis and ureter, Wassermann and Cederkreutz in urethral carcinoma. Scholl and Braasch adopted this view and say that Kittel and Kaufmann demonstrated definite epithelioma associated with urethral stricture, but that Thiersch was the first to call attention to malignant transition of these cicatrized areas and to report a case of squamous cell epithelioma developing in a case of long-standing stricture. In 1904 Poesner collected 20 cases in the male urethra, in 12 of which urethral stricture had been present. Other authors have reported cases in which carcinoma followed traumatism, generally to the perineal urethra. Kretschmer admitted that stricture often led to metaplasia or leucoplacia of the urethral mucosa, but he asserted that carcinoma may produce symptoms of stricture early in its course and lead to an erroneous diagnosis. In a paper by Kretschmer we read that since "gonococcal infection of the male urethra is common and carcinoma rare, the gonococcus plays little if any etiologic rôle in the production of this disease."

PATHOLOGY

Primary carcinoma of the male urethra has been classified as follows (1) squamous cell, (2) columnar cell, (3) papillary, and (4) adenocarcinoma. All authors are agreed that the squamous cell carcinoma is by far the most frequent (in Preiswerk's series of 42 cases, all but one). In Kretschmer's series of 80 cases he found none of the columnar type and considered that the papillary carcinoma, of which he presented a case, was also very rare. When adenocarcinoma was found, the origin was thought to have been Cowper's glands in most cases, but it was admitted that a true adenocarcinoma might begin in other peri-urethral glands, although this apparently was extremely rare. In a study made by Young and Davis (1926) it was stated that "metastases in epithelioma of the urethra are usually late. Regional metastasis is to the iliac or inguinal nodes, or both. If the growth is posterior to the suspensory ligament, there is little chance of metastasis to the inguinal nodes. From the urethra lymphatic drainage goes to the external iliac, hypogastric, and sacral groups of nodes so that any of these may be involved. In 2 cases

Fig. 5. 1. Left crus being divided. 2. Clamp has been placed in front of urethra just below bulbomembranous junction and bulb is being divided. 3. Large cavity left after removal of urethra and 3 corpora with surrounding fasciae intact. Two ends of urethra are about 3 1/2 inches apart (9 cm). Problem was what to do to close external defect. BUI 26189

Harbach added 7 cases which had been collected by McNally and 1 by himself bringing the total number in the literature to 107. In 1938 Hertzmann and Colloff stated that after a very thorough search of the literature they found 143 reported cases many of which had not been mentioned by any authors since the original publication. To this list they added 2 new cases making the total of 145 reported to date. When one considers the number of papers that have been written on the subject the fact that only 145 cases have been reported is sufficient to show the comparative rarity of the disease. At this clinic we have had 84 cases of carcinoma of the penis, but only 5 cases of carcinoma of the urethra.

In the early literature Thaudere was given credit for the first report of carcinoma of the urethra. There was an obstruction in the spongy urethra at a depth of about 1 1/2 inches. The author incised the superior surface of the glands, dissected out the tumor which was the size of a pea from the wall to which it was adherent. Kurwin after

studying the original report decided that, as the patient was a young man and was cured by a small excision of tissue and cauterization, the case could not be accepted as one of carcinoma. The first apparently acceptable case was that of Hutchinson which was presented to the London Pathological Society in 1861 but the first paper of real importance was that of Wassermann, who presented, in 1895, 20 cases in the male 24 in the female and 3 cases in which the lesion was located in Cowper's glands. Since then the literature contains papers by Soubeyran (1902), Lanton (1910), Scholl and Braasch (1922) and the papers by Kretschmer and the others mentioned above to which publications the reader is referred for complete bibliographies.

ETIOLOGY

Inflammatory irritation causing metaplastic changes in epithelial surfaces has been cited as the principal etiological factor by numerous writers. Böhm thought that this was the cause of carci-

Kretschmer (1923) reported a case of carcinoma of the urethra in which he had carried out amputation of the penis, transplantation of the urethra to the perineum, and removal of the inguinal glands *en masse*. Similar operations by various authors are to be found in the literature.

Emasculatation has been frequently performed by European surgeons, but no evidence of involvement of the testis is found in any of the reported cases. Lower (1931) reported 3 cases.

His first was a "man aged 58 who suffered injury to the perineum some years previously. Two years before admission he had an acute retention caused, he said, by a cyst of the urethra. The perineal incision had been made. This was followed by fistula. Acute retention was present. A suprapubic puncture was made. Later an operation was undertaken for the relief of stricture. I was not sure that the condition was malignant, although it was unusually hard. The operation consisted of opening the bladder and passing a sound retrograde. At the tip of the sound in the perineum the urethra was divided. The mass was dissected free and the distal end of the urethra severed beyond the involved tissues. About 1 5 inches of urethra was resected. By passing a number 18 catheter from the meatus, an end-to-end anastomosis was made. Convalescence was rather slow, but after a reasonable time the catheter was removed. The small perineal fistula remained but soon closed. Regular dilatation has been continued. The patient is in good physical condition and there is no evidence of recurrence after 9 years." The histologic diagnosis was squamous cell carcinoma.

Lower's Case 2 "A man aged 40 had gonorrhea at 22. Eleven years before he had acute retention which was relieved by perineal incision followed by a stricture requiring frequent dilatations. Acute retention was present and I was unable to pass any instrument through the stricture. A suprapubic puncture was done. A very indurated area was found in the perineum. A diagnosis of malignancy was made. A resection was done as in the previous case and x-ray therapy given. A union at the point of anastomosis at the ends of the urethra was not very satisfactory and a tight stricture resulted. Internal urethrotomy was performed 2 years later and since then dilatation at regular intervals has been done. There is no evidence of recurrence after 8 years." Histologic diagnosis: papillary carcinoma.

Lower's Case 3 "A man, aged 61 years, had gonorrhea at the age of 25. He was admitted with difficulty of urination. "An extensive induration was present in the perineum extending along the entire urethra. The inguinal glands on both sides were involved. Biopsy of the gland showed malignancy. Nothing short of an extensive block dissection seemed worth while. The penis, testes, and inguinal glands on both sides were removed and the urethra transplanted into the perineum. Bilateral hernias were present which were successfully corrected after the testes and inguinal glands were removed. It is now 3½ years later and there is no evidence of recurrence."

As shown by the literature, the operative results have been far from satisfactory. Of the 72 cases collected by Watson 79 per cent of the patients were dead within 6 months. Diehl puts the mortality rate at 80 per cent. Kreutzmann and Colloff in January, 1938, stated that they found

Fig 9 Photograph taken 7 months after operation showing great shortening of penis. BUI 26189

143 cases of carcinoma of the male urethra in the literature. For clinical purposes they listed the growths into "two main groups, depending on their location: (1) those occurring in the anterior or penile portion of the urethra, and (2) those found in the bulbomembranous or posterior portion. Anatomically, the bulbous portion is not a part of the posterior urethra, but for a study of their results, this arbitrary division is a rational one. In 60 of the 143 cases the carcinoma occurred in the anterior portion of the urethra. Seventy-eight patients had carcinoma of the posterior portion of the urethra. The growth was found most often in the bulbous or membranous part and occasionally in the prostatic part." The different forms of treatment described are "suprapubic cystostomy, internal or external urethrotomy or both, incision and drainage of the perineum, resection of the urethra and the growth, fulguration and application of radium, excision of the inguinal or the deep femoral glands, total emasculatation, passage of sounds and the use of an indwelling catheter. In this series of 78 patients with cancer of posterior regions only 11 (14.3 per cent) recovered, while 58 (74 per cent) died. In 9 (11 per cent) there was no mention of the end-result. The operation which gave the greatest number of cures was resection of the urethra with the included growth. This was performed in 5 [cases of Lower, Sokolov, Scholl and Braasch, and Oberlander]. In 1 of the 5 the inguinal glands were removed. In a second the penis was amputated and in a third radium was applied after operation. In contrast to the gratifying end-results obtained in the treatment of the growths involving the anterior portion of the urethra, carcinoma of the posterior portion possesses a gloomy picture."

RÉSUMÉ

A thorough study of carcinoma of the male urethra is to be found in recent literature. Our

Fig. 8 Comparative views of penis before and after operation. Only glans and small portion of shaft were visible after operation. BUI 26189

cited by Imbert metastasis to the testis and in another to the bladder were present. In several reports in the literature in which cases of epithelioma of the pendulous urethra are cited, metastasis to the inguinal glands were found, and most authors are agreed that if amputation of the penis is done, removal of the inguinal nodes, preferably a block dissection along with the penis should be carried out. Lazarus stresses the importance of employing the technique of block dissection devised by Young for carcinoma of the penis and reports a case in which he employed this method.

OPERATIVE TREATMENT

Kretschmer expressed the generally accepted surgical opinion in 1923 as follows: 'Just as soon as the diagnosis has been made nothing short of a radical operation should be employed viz amputation of the penis with transplantation of the urethra and complete extirpation of the inguinal glands.' This opinion has been concurred in by various writers since that date. Some of the early authors advised complete emasculation but recent writers have agreed that such mutilation is not helpful or necessary. Huggins and Curtis (1929) stated that for lesions of the anterior third of the urethra simple amputation should suffice but that for urethral carcinoma between this point and the membranous urethra more extensive removal with perineal implantation of the urethra was indicated and that for cavernous lesions the entire penis with crura and urethra down to the membranous urethra should be excised. They reported a case in which this very extensive and mutilating procedure was carried out. In the older literature cases are reported in which excision of

the carcinomatous area through the perineum with cauterization of the wound was carried out.

A detailed study of cases of squamous carcinoma of the bulbous portion of the urethra was made by Marcus Beck in 1892. All the cases were inadequately treated except possibly that of Mikulicz, which was as follows:

In 1883 Mikulicz operated upon a patient with carcinoma of the bulbous urethra. There was a fistula present which was laid open thus exposing a cavity the size of a hen's egg. When the superficial granulations were scraped away, a tissue was exposed resembling squamous carcinoma of the lip. The whole penis with the crura was removed but recurrence took place in 4 months. Microscopic examination proved the growth to be a squamous carcinoma.

Oberlaender (1893) reported the case of a man aged 76 years, who had been treated for 4 years for a stricture of the urethra. It was discovered by endoscopic examination to be carcinoma. The tumor was in the region of the bulb the size of a chestnut and somewhat lobulated. It was excised with the urethra 1.5 to 2 centimeters above and beneath the tumor. The ends were closed together with catgut sutures. Healing followed by primary intention in 3 weeks. The extirpated inguinal glands were negative. In 7 months the patient returned with a local recurrence which was easily palpable and visible endoscopically. Examination of the specimen showed around the lumen of the urethra a half circular tumor 4.5 centimeters long and 2.3 centimeters thick. Microscopy showed flat epithelial cells. (Comment by H.H.Y. It is evident from the description that the corpora cavernosa were not removed.)

In 1922 Scholl and Braasch reported a case of a man with a hard nodular mass 2 centimeters in diameter in the perineum at the penoscrotal angle associated with a tight stricture of the urethra. 'At operation a growth 4 centimeters long was found at the junction of the membranous (bulbous?) and anterior portions of the urethra. The involved area was completely excised. Later complete emasculation of the penis and testicles with dissection of the inguinal glands was advised but refused by the patient. The specimen showed an irregular firm tumor about 3 centimeters in diameter—a squamous cell epithelioma. Six weeks later the urethra was reconstructed from a section of the internal saphenous vein. Two months later the area had completely healed save for a persistent perineal sinus. Radium (350 mgh) was applied to the urethra in the region of the scar through the perineal sinus. The patient was alive at the end of 5 years.'

FRACTURES OF THE NECK OF THE FEMUR

Open Operation and Pathologic Observations. A New Incision and a New Director For The Use of a Simplified Flange

WILLIAM R CUBBINS, M D , F A C S , JAMES J. CALLAHAN, M D , F A C S., and
CARLO S. SCUDERI, M.D , F A C S , Chicago, Illinois

EVEN before the days of Delbet, it is probable that men were attempting to apply some form of internal fixation for fractures of the neck of the femur to facilitate union and to shorten the disability.

However, our present concept of the operative treatment of this most difficult fracture has, with few alterations, been handed down from Delbet. He used bone grafts, nails, screws, and whole grafts of the fibula. Since then, many men, time and again, have advocated the use of these methods, only to have them fail to produce good results, apparently because of the failure of the proximal fragment to live and produce new bone.

In relation to the origin of directors for forcing bone or some other foreign material into the femur, we are also indebted to Pierre Delbet for having devised the first mechanical apparatus to aid the insertion of any material for internal fixation. It was first described in 1911 and was called the *canon de Delbet*.

Charbonnier also made a rather simple appliance, using the spine of the ilium and the symphysis pubis as the fixed points and then, by the use of a movable perpendicular third part, marking the center of the head so that a drill hole could be guided by this marker. Charbonnier described this apparatus first in 1923 and then again in 1932.

Hustin and Leemans, in 1933, used a rather crude guide for boring a hole into the head, but it was not an instrument of accuracy in any sense of the word. Sterling Bunnell, of San Francisco, also devised a director of almost mathematical perfection and published a description of it in the same year. In 1934, Brocq and Dulot, and Denis described ingenious devices for pegging the neck of the femur which required only a small lateral incision, just large enough to permit a drill, and a small anterior incision over the neck of the femur, which was used to direct it. None of these devices required an extensive arthrotomy.

In 1928, Smith-Petersen devised a three-flanged nail with a head. He made an extensive open

From the Fracture Ward, Cook County Hospital

arthrotomy and, after alining the fragments of the fractured neck, inserted the three-flanged nail. This method has without question given excellent results and many men have verified the results obtained and published by Dr. Smith-Petersen. However, the difficulty in this operation is that the nail does not always travel in the desired course, in the hands of some operators it has been almost impossible to make the nail take the desired course. It is because of the excessive cost of the Smith-Petersen nail and the difficulty of always directing it correctly that we have been stimulated in our research in an effort to produce a simpler nail or flange which could be used with a director. In our opinion, however, Smith-Petersen's original idea that an arthrotomy is essential to the accurate apposition of the fragments in a case of fractured neck of the femur is fully justified. We find that while certain types can be reduced into almost perfect position by closed manipulation, in other types either a spicule from the proximal fragment or a spicule from the distal fragment has pierced the capsule in such a manner that re-apposition of the fragments into proper position by closed manipulation is utterly impossible. We have been able also to demonstrate, in a certain number of cases, a very definite interposition of the periosteum and synovia detached from either the proximal or distal fragments and dislocated between these fragments in such a manner that it could, without question, prevent union if it were not removed at open operation.

In the spring of 1934, Dr. Ottolenghi, of Buenos Aires, demonstrated a guide or director which he and Dr. José Valls had constructed. This device appealed to our imagination, and upon its basis of construction Dr. Scuderi proceeded to modify the apparatus as here described.

The flanges are made of stainless steel. They embody all of the advantages of the Smith-Petersen nail, from which they have been copied, and, in addition, their utter simplicity of shape and ease of manufacture reduce the cost of manufacture to a minimum (Figs. 1 and 2).

paper is intended primarily to discuss the operative treatment of carcinoma of the bulbous urethra, but we have referred briefly to carcinoma of the penile and also of the membranous urethra. The accepted operative procedures, as outlined by various authors for carcinoma of different parts of the urethra have been given.

Cases of carcinoma of the bulbous urethra that have been subjected to radical operation have been quoted in detail.

From these studies it seems evident that the technique employed in the case which forms the basis of this report is the only one in which a large growth involving the three cavernous bodies in the bulbous urethra has been radically excised with all three cavernous bodies but without removal of the penis. This was accomplished by division of the urethra and three corpora anteriorly at the penoscrotal juncture and posteriorly close to the membranous urethra. The great defect produced by this extensive removal of the urethra and three corpora has for the first time been closed by pulling back (telescoping) the penis and anastomosing it to the stump of the bulbous urethra near the triangular ligament.

It seems that this technical procedure has not previously been carried out. The ease with which it can be accomplished and the elimination of the great urethral defect by means of backward displacement of the shaft of the penis and anastomosis of the penile urethra to the bulbomembranous urethra are remarkable factors.

This operation might also be applied satisfactorily to urethral carcinoma of the scrotal and upper penile portions, and thus perineal transplantation of the stump of the urethra and loss of the penis avoided. Total emasculation is thus avoided by this new operation.

CONCLUSIONS

Study of the 145 cases of carcinoma of the male urethra shows that the larger proportion are situated back of the penoscrotal juncture.

Early radical operation is recognized as of prime importance when the lower penile urethra is alone involved. Amputation in continuity with block dissection of inguinal glands is the accepted procedure.

For carcinoma farther up the urethra (high penile and bulbous), complete removal of the penis and bulbous urethra, in part, with transplantation of the posterior portion into the perineum has been the accepted procedure.

For these cases a new method is proposed by means of which the penis is spared and the great defect, left after removal of the bulbous and scrotal portions of the urethra along with the three cavernous bodies, is done away with by drawing the penis back into the perineum and suturing it to the bulbomembranous urethra and triangular ligament. This operation allows more radical excision of the perineal structures involved and avoids amputation of the penis, or plastics which lead to sticture. It is both radical and conservative.

I wish to thank Dr. Wyland F. Leadbetter, resident urologist, for much assistance and Mr. William F. Dicusch for the beautiful drawings which have so completely illustrated our operative technique.

Fig 8 This drawing shows the line of dissection in an approach to the hip. Although several artistic liberties have been taken in order to portray the details which we desired, in the main the essentials of the exposure are well presented

so that it must follow the course governed by the directing bar (Fig 3)

On the front end of the directing block is a sharp prong which is driven into the shaft of the femur just below the trochanteric bulge, so that the flange will travel into the head in a valgus position

When both the prong of the directing bar and the directing block have been firmly fixed, the thumb screw on the top of the block is tightened so that no slipping can occur. The number of the flange to be used in any specific case is indicated by reading the number on the top of the directing bar. If the specific length of flange indicated is used, one is assured that the flange will be long enough to reach the head of the femur and yet not perforate the acetabulum.

Occasionally the cortex of the femur is very hard and will turn the edge of the flange. A starting chisel (Fig 4) may be used in such cases to make the original cut in the cortex, the flange will then go in with greater ease and accuracy.

In either the adolescent or an old woman in whom the femoral neck is very thin, a flange of greater width is apt to cause fragmentation of the femur, therefore a narrower flange is recommended. The director is made to accommodate the different flanges, when the narrower flange is used a small metal adaptor is shipped into the directing block to hold it firmly.

The flange is inserted into the directing block and a punch with slotted handle called the inserter (Fig 5), is fitted over the end of the flange. With a mallet the flange is driven in. The inserter serves three purposes: (1) It prevents the formation of a burr on the hammered end of the flange; (2) After the flange is completely driven in, by means of its shoulder the inserter prevents the holes in the head end from being buried; (3) A few mallet blows on the inserter impacts the fracture surfaces together.

When the flange has been driven about two-thirds of the way in, it no longer can change its course. The director is removed so that the flange

Fig 1 Four juvenile size flanges π of varying lengths $3\frac{1}{2}$ $3\frac{1}{4}$ 4 $4\frac{1}{4}$ $4\frac{1}{2}$ inches in width. The flanges are made of stainless steel.

Fig 2 Four adult size flanges π of varying length $3\frac{1}{2}$ $3\frac{1}{4}$ 4 $4\frac{1}{4}$ $4\frac{1}{2}$ inches in width made of stainless steel.

The flanges are made in four lengths $3\frac{1}{2}$, $3\frac{3}{4}$, 4 and $4\frac{1}{4}$ inches, and in two widths $\frac{3}{8}$ inch (for the adolescent and the aged women with very narrow femoral necks) and $\frac{1}{2}$ inch (for the average adult with a normally thick femoral neck).

This director was devised with the hope of facilitating the accurate pegging of the fragments—a difficult procedure even when the hip joint has been widely exposed. The director is quite different from the original shown by Drs Valls and Ottolenghi.

Fig 3 Assembled director ready for use with either width flange.

Fig 4 Starting chisel.

Fig 5 Insertor.

Fig 6 Extractor.

The directing bar has a long sharp prong which is inserted into the anterior lip of the acetabulum, so as to bisect the head. On its top surface are the markings 1 2 3 4 which indicate the length of nail necessary accurately to peg the head fragment. The directing bar has a handle to stabilize it during its use and to facilitate its handling.

The directing block is manipulated in much the same manner as are the sights of a rifle except that it is movable instead of fixed to the barrel. The directing block keeps the flange in a groove.

Fig 11 Reveals curtain between fragments

limb is fixed in extension in a Thomas splint. If bed sores or other conditions prevent the patient's lying on his back continuously, it is possible to dispense with the traction and to allow the patient to be free in bed and be turned to the opposite side or down on the face. The patient is usually returned to the ward, where about 7 to 10 pounds of weight with the limb in extension is used for a period of 10 to 14 days. After this period only thigh extension is used and by means of a Pearson attachment the knee function is resumed. At the end of 3 to 4 weeks all extension is discontinued. Patient then lies flat in bed, and 7 to 10 days later he may be up and around in a walking caliper, which can be removed at night.

When bone growth occurs early, which can be demonstrated with the x-ray, walking on the limb operated upon is permitted at the end of 6 months. But, if no bone growth is evident, longer periods with the caliper are necessary. Usually at the end of 7 to 9 months a bursitis develops over the end of the flange, causing considerable discomfort to the patient. If there is adequate bony union, the flange should be removed. This can be easily done under local anesthesia. In some instances, the flange works itself into the subcutaneous tissues, this necessitates removal.

Our first and most startling observation is that, irrespective of the apparent transverse line of fracture of the neck of the femur according to the x-ray, it is not uncommon to find at the time of operation that there is more or less obliquity. This obliquity is most commonly characterized by a long anterior spicule on the proximal fragment. However, this particular type of obliquity varies in every direction, from above down, from below up, and from before backward. This fact has been

Fig 12 Fracture with intact, periosteosynovial membrane

emphasized by Dr. Paul B. Magnuson. We have observed other common variations, in which there have been spicules of bone on these fragments, varying in length from $\frac{1}{2}$ to $\frac{3}{4}$ inch and yet the fragments appeared from the x-ray study to be perfectly transverse.

Another observation which must be carefully mentioned is that the long fragments, particularly when they are on the anterior surface of the proximal fragment, can and do pierce the Y ligament of Bigelow at its middle or at its lower attachment to the femur in such a manner that it is almost impossible to reduce it by any type of manipulation. We have not as yet been able to demonstrate this type of perforation in the posterior portion of the capsule.

Fig 13 Typical interposition, as seen in old cases

Large portion of periosteal-synovial membrane detached from proximal portion of distal fragment

Fig 9 Detachment of periosteal synovial membrane from the proximal portion of the distal fragment

can be driven in the remainder of the way. A thumb release is on the right hand side of the directing block to facilitate its removal if the flange fits too snugly into the block.

Should the flange accidentally be driven in correctly, and one desires to remove it, it can be removed by the use of the simple extractor (Fig 6). The small prong is inserted through the hole in the flange, and it is hammered out (Fig 7E).

SURGICAL APPROACH

The incision (Fig 8) we have found to be the best in these operations has been developed in the anatomical laboratory by Dr Callahan. The skin incision is made from the anterior superior spine downward toward the knee for a distance of about 8 inches and it then dips posteriorly with a hockey stick curve. The line of cleavage between the sartorius and the anterior border of the tensor fasciæ femoris is then found and this border of the tensor fasciæ femoris is followed until its lower end reaches its fascial attachment. This fascia is then cut transversely and the gluteus medius and tensor fasciæ femoris are retracted posteriorly while the rectus femoris is retracted medially. At this point, the operator can see the branches of the lateral circumflex femoral vessels which can be clamped and tied before they are cut. As a rule there are two or three other small branches which can also be seen and clamped before they are cut. In this manner, an almost bloodless approach to the neck of the femur can be made.

The lateral portion of the rectus femoris and the belly of the iliacus are retracted medially

Small portion of periosteal-synovial membrane detached from proximal portion of distal fragment

Fig 10 Fracture similar to that in Figure 9 with small portion detached

thus exposing the capsule covering the hip joint. The capsule is then incised in the course of its fibers from the acetabular rim down to its insertion into the intertrochanteric region of the femur. Later the capsule may be incised as is necessary, but this method preserves the landmarks. The capsule is then detached from its anterior femoral insertion in such a manner that the fragments are exposed and brought into full view.

If the fragments have not been brought into contact by the manipulations previous to the open operation, at this point they are exactly opposed. In this way, the greatest possible area of bone surface is brought into contact.

When the fragments are in exact apposition, a longitudinal incision is made in the vastus lateralis in the direction of the fibers just below the greater trochanter and the underlying femur is exposed. The long prong of the directing shaft is now inserted into the edge of the acetabulum (Fig 7A).

The directing block is then fixed in the shaft of the femur just at or below the bulge of the trochanter major by placing the prong of the directing block through the opening made in the vastus lateralis. This is locked to the directing shaft by turning the thumb screw on its top. The flange is now inserted through the directing block and driven home with the inserter (Fig 7B).

The capsule is replaced and loosely sutured. The wound is closed with interrupted catgut sutures and Michel clips or silk sutures are used for the skin. Buck's extension is applied and the

Fig 15 A, J L, aged 60 years Injured May 5, 1935 Roentgenogram shows the position of the fracture after the patient had been in traction a few days Please note that this is a long oblique fracture with a sharp spicule on both the proximal and distal fragments B, Patient was operated upon June 19, 1935 This figure shows the position immediately following the operation with the flange inserted Note the complete change in contour of neck and

the impossibility of recognizing the sharp fragments, because they had been accurately reduced The flange was a little too long for this neck C, Walking was permitted October 5, 1935 This film was taken January 8, 1936, shortly after the removal of the flange One can see the groove through the neck of the femur where the flange had formerly been Close examination shows a complete restoration of the trabeculae through the neck

It is not as yet possible to discuss the final outcome of the cases in which this aseptic necrosis has been definitely proved to be present by microscopic examination This will be discussed in a later communication

RESULTS

Up to January, 1938, we have operated upon 105 patients with fracture of the neck of the femur Ninety of these were openly reduced within the first 2 weeks Fifteen operations were performed from 5 weeks to 6 months following injury The age of the patients varied from 14 to 82 years, this includes both males and females Shock did not occur in any of our patients following open arthrotomy We have had 1 death caused by overlooking a point of infection on the leg, below the hip joint operated upon In this patient operation was followed by infection and exitus

There were 3 contracted hips in patients in whom the capsule had been left open Although these contractions occurred late—1 a convalescing patient with pernicious anemia and the 2 others individuals who developed senile dementia—the possibility that an excessive development of scar tissue in the open capsule might be a cause should be considered

In 2 cases the femoral head was resorbed following the operation The flange worked loose and was extruded one-half its length outside of the shaft The femoral neck in one woman was partially absorbed, but the femoral head was viable, and she has had a painless useful limb, with 1 inch of shortening We believe these 3 cases must be classed, 2 as failures and 1 as fair, and that they are the result of inaccurate apposition of the fragments or unobserved interposition

This is a total of 7 unsuccessful results: 1 failure, 1 death, 2 non-unions, and 3 hip contractures It seems to be true that the early surgical treatment with correct replacement of the fragments has a very favorable effect upon the viability of the femoral head, as up to the present time over 90 per cent of all these early operations have been successful (Figs 14 and 15). We are convinced, although without microscopic proof, that many so called cases of aseptic necrosis of the head have undergone a rapid creeping substitution, with an early exact approximation of the fragments.

SUMMARY AND CONCLUSIONS

1 We have operated upon 105 patients with no shock and only 1 operative death The ages of the patients varied from 14 to 82 years, and even though the mortality rate has been low, we have

Fig 14 A B C aged 27 years. Injured August 24 1935. Roentgenogram shows a transverse subcapital fracture of the neck of the femur apparently in good position. The head appears viable. Operation was performed September 5 1935. B Taken September 8 1935 3 days after operation. Note an apparent filling defect of the

inferior margin of the neck. This was caused by a loss of bone tissue. Patient was discharged from the hospital on October 30 1935. C Taken on June 4 1936 shows the flange removed and a complete bony union of the fracture line. There has been a filling in of the bone defect as seen in Figure 14 B. Valgus position has been maintained.

We have also noticed sheets of the periosteum and synovia detached from the proximal portion of the distal fragment (Fig 9) dropped as a curtain down between the fractured ends of the femoral neck. This same phenomenon has been observed when the periosteal synovial membrane has been detached from the osteocartilaginous line of the proximal fragment and also fallen as a curtain between the fragments (Fig 10). We also have had 2 cases in which the osteoperiosteal membrane has been completely detached from both fragments and dropped between the fractured surfaces. These pieces of periosteal synovial membrane vary in size from a ribbon shaped piece about $\frac{1}{4}$ inch wide to a curtain $1\frac{1}{4}$ inches wide and 1 inch long (Fig 11).

Incomplete fractures of the neck of the femur are not uncommon. We have had four in patients over 60 years of age in whom there was a fracture of the anterior surface of the femoral neck distinctly subcapital in which there was not a complete separation of the periosteal synovial membrane on the posterior surface of the femoral neck (Fig 12). In other words the posterior portions of the fragments had been held in contact by the periosteal synovial membrane.

In 1 patient upon whom we operated late we have every reason to believe that a large curtain had fallen in between the fragments and caused a non union (Fig 13).

Regarding the Leadbetter method of reduction of a fractured neck of the femur, we are convinced

that when the capsule has been perforated by the sharp spicules either from the proximal or distal fragment it is not possible to bring about reduction by any closed method. In fact, in a series of about 35 cases, the reduction in nearly one half of them was not perfect by any manner of means as we found when the joints were opened by the Callahan incision which revealed the entire anterior portion of the joint.

We have attempted to prove the viability of the head by taking a scoop of the cancellous bone and then having multiple microscopic sections made from this specimen. In some of these there has been an aseptic necrosis of both the head and the proximal portion of the one distal fragment. We are not as yet prepared to state that this aseptic necrosis is not the same type of necrosis which is so common in the ends of all fractured bones. In some sections removed from apparently aseptic necrotic heads, the heads have lived and produced bone.

The amount of blood and blood clots which are found in the joint that is opened in 1 to 2 weeks is an excellent indication of the viability of the proximal fragment. In some joints there is only a small amount of bloody serum with few if any small clots. The microscopic examinations of bone removed from both proximal and distal fragments in these cases have shown a definite aseptic necrosis or as we prefer to call it dormant bone to be present both in the proximal and distal fragments.

TECHNIQUE OF ANASTOMOSIS USING THE STONE CLAMP

JAMES C OWINGS, M D , and HARVEY B STONE, M D , F.A.C.S , Baltimore, Maryland

SINCE the recent publication of the short preliminary article (2) showing the details of construction of a new clamp for performing aseptic end-to-end anastomoses, we have modified the technique considerably and have also used this clamp for lateral anastomoses, end-to-side anastomoses, and for operations involving resection of the stomach. It also works very nicely for the excision of Meckel's diverticula. We feel that we have now had sufficient experience with these various procedures both clinically and experimentally to make a detailed description of the technique of some lasting value. It would seem essential that these details be put before the public as soon as possible because of the spreading use of the new instrument. All of the changes which we have made have been to render the operations less difficult and make them safer. We feel that it is absolutely essential for anybody using this clamp to understand and follow the details of technique as exactly as possible if uniformly successful results are to be expected. For the purpose of exhibiting these techniques in detail we have had prepared a fairly large series of drawings which are published herewith.

Figure 1 shows the mesentery of the small bowel divided down to the marginal vessel which is shown isolated and tied but not yet divided. The actual isolation and tying of this vessel, thereby giving free exposure to the muscle of the bowel wall at the site of the contemplated resection, is

From the Surgical Hunterian Laboratory of the Johns Hopkins Medical School

quite essential, not only from the viewpoint of giving adequate exposure for the laying of the sutures at a later step, but also for the prevention of damage to the blood supply at the site of the future anastomosis by blind clamping or hematoma formation, either of which at any stage of the operation might so embarrass the blood supply as to make the suture line unsafe. When this vessel is isolated and tied ahead of time, if any such accident should occur, the site of the resection can be readily changed without any loss of time. In choosing the site for the resection it is well if possible to pick a point very close to one of the larger mesenteric vessels so that adequate blood supply is assured. The bowel is crushed with an ordinary Kocher clamp before the application of the resection clamps. The resection clamp is oiled, before being applied, to prevent sticking. A Kocher clamp is placed on each end of the segment to be resected as close to the resection clamp as possible, and the bowel is cut flush against the resection clamp with the actual cautery. If there is disproportion, the clamp on the segment with the smaller lumen can be applied obliquely toward the antimesenteric border in order to increase the size of its lumen.

Figure 2 shows the bowel divided and the segment which was to be resected removed, with the ends of the bowel being brought together for the anastomosis. It will be noted that instead of the clamps having been applied in a line parallel to the mesentery as is the common practice today, they are applied at right angles to it. So far as we

Fig 3

Fig 1 The mesentery is divided down to the marginal vessel which is shown tied but not divided

Fig 2 The diseased segment has been resected. The ends of bowel are being brought together for anastomosis, the resection clamp is applied at right angles to mesentery

Fig 3 The posterior layer of the continuous silk suture has been laid but has not been completely pulled down as yet. The inset, upper right corner, shows the resection clamps placed parallel with the mesentery which we consider to be the wrong position

no illusions as to the inability of aged patients to withstand the shock of any operation

2 The incision gives excellent exposure with a very small amount of bleeding

3 The director is of the greatest possible value in accurately approximating and holding the fragments in position, and we are sure that early careful approximation and fixation are of the utmost importance if we are to expect a good growth of bone

4 Convalescence is much more rapid and the patient is far more comfortable than he has been with any previous method in our hands. In addition he has been saved thousands of bed hours in the hospital

5 This method has not been so successful in fractures of long duration, in spite of most accurate approximation in some cases there has not been an adequate amount of bone growth to keep the fragments firmly together. Slipping and loosening in old fractures have occurred just as with any other method of fixation

6 Results have been better in those patients in whom we have had a persistent valgus position

7 The flange is more easily and accurately applied than a screw, and we believe holds more firmly

8 In 90 per cent of the fresh fractures bony union resulted

TECHNIQUE OF ANASTOMOSIS USING THE STONE CLAMP

JAMES C OWINGS, M D , and HARVEY B STONE, M D , F A C S , Baltimore, Maryland

SINCE the recent publication of the short preliminary article (2) showing the details of construction of a new clamp for performing aseptic end-to-end anastomoses, we have modified the technique considerably and have also used this clamp for lateral anastomoses, end-to-side anastomoses, and for operations involving resection of the stomach. It also works very nicely for the excision of Meckel's diverticula. We feel that we have now had sufficient experience with these various procedures both clinically and experimentally to make a detailed description of the technique of some lasting value. It would seem essential that these details be put before the public as soon as possible because of the spreading use of the new instrument. All of the changes which we have made have been to render the operations less difficult and make them safer. We feel that it is absolutely essential for anybody using this clamp to understand and follow the details of technique as exactly as possible if uniformly successful results are to be expected. For the purpose of exhibiting these techniques in detail we have had prepared a fairly large series of drawings which are published herewith.

Figure 1 shows the mesentery of the small bowel divided down to the marginal vessel which is shown isolated and tied but not yet divided. The actual isolation and tying of this vessel, thereby giving free exposure to the muscle of the bowel wall at the site of the contemplated resection, is

From the Surgical Hunterian Laboratory of the Johns Hopkins Medical School.

quite essential, not only from the viewpoint of giving adequate exposure for the laying of the sutures at a later step, but also for the prevention of damage to the blood supply at the site of the future anastomosis by blind clamping or hematoma formation, either of which at any stage of the operation might so embarrass the blood supply as to make the suture line unsafe. When this vessel is isolated and tied ahead of time, if any such accident should occur, the site of the resection can be readily changed without any loss of time. In choosing the site for the resection it is well if possible to pick a point very close to one of the larger mesenteric vessels so that adequate blood supply is assured. The bowel is crushed with an ordinary Kocher clamp before the application of the resection clamps. The resection clamp is oiled, before being applied, to prevent sticking. A Kocher clamp is placed on each end of the segment to be resected as close to the resection clamp as possible, and the bowel is cut flush against the resection clamp with the actual cautery. If there is disproportion, the clamp on the segment with the smaller lumen can be applied obliquely toward the antimesenteric border in order to increase the size of its lumen.

Figure 2 shows the bowel divided and the segment which was to be resected removed, with the ends of the bowel being brought together for the anastomosis. It will be noted that instead of the clamps having been applied in a line parallel to the mesentery as is the common practice today, they are applied at right angles to it. So far as we

Fig 9

Fig 10

Fig 11

Fig 4 The anterior layer of No. 0 chromic catgut is shown laid. The handles of the clamp have been omitted for the sake of clarity.

Fig 5 The clamps have been released and are being withdrawn together as the anterior layer is pulled tight to

complete the first layer of the anastomosis. Note the application of the handles to the opposite end of the blades to facilitate this maneuver.

Figs 6 and 7 The beginning of the anterior layer of mattress sutures is shown. The first stitch is used to invert the knot where the catgut has been tied to the silk and is left long for traction as indicated in Figure 7.

Figs 8 and 9 The method for gaining exposure to the posterior surface of the bowel is shown. One of the sutures which has been left long is passed through the rent in the mesentery and by making gentle traction in opposite directions on both sutures the bowel is turned upside down as shown in Figure 9.

Fig 10 This inset merely shows an enlarged view to emphasize the importance of laying one mattress suture directly at the mesenteric border.

Fig 11 The anastomosis is shown completed and the rent in the mesentery is being closed. Note that the eye of the needle instead of the tip is used for sewing.

Fig 12 This figure shows the closure of the triangular space at the border of the mesentery on the opposite side from Figure 11.

Fig 13

Fig 14

Fig 15

Figs 13, 14, and 15 These three drawings illustrate the method used to perform an aseptic lateral anastomosis. They are self explanatory. The procedure from this point is completed in the same manner as in the end-to-end anastomosis.

know this method of application is new, although it has probably been used many times and never reported. We think that it is a very important step in the technique of doing an end-to-end anastomosis because it gives so much better exposure to the mesenteric border, which is always the hardest point to handle because of the danger of leakage and possible damage to the blood supply. With the clamp placed in this manner the bowel wall can be exposed down to the muscle and the suture lines laid to the desired depth without danger. If one is using the clamp for a Parker-Kerr type of inversion, this method of application is also of great value because it places the mesentery in the center of the clamp where it is easy to invert instead of at the tip where it is next to impossible to invert. This technique is being taught the Hopkins students, but we have never seen it pictured or described in any of the current textbooks or systems of surgery. One of us (Owings) started to teach this method in 1927.

Figure 3 shows the posterior line of continuous silk laid but not yet pulled down tight. The handle of the clamp has been omitted for the sake of clarity. The inset in the corner is merely made to emphasize the common way of applying the clamps which we consider to be the wrong way. It shows the clamps placed parallel with the mesentery, the mesentery being held in the tip of the clamp.

Figure 4 shows the posterior layer of silk pulled down and tied and the anterior layer of No. 0 or No. 00 chromic catgut laid over both clamps but not yet pulled down. We are using chromic catgut in this anterior layer instead of silk for two reasons: first, it is stronger, and, second, it slides more smoothly. Silk has a tendency to grab and because of this to pull down tight at both ends leaving the middle loose and improperly inverted. Chromic catgut overcomes this difficulty.

In Figure 5 the clamps have been released from the crushed edge of the bowel and are being withdrawn together. The handles of the clamps have been removed from the tip and placed on the hinge to facilitate this procedure. The anterior suture of catgut is being pulled down as the clamps are withdrawn to complete first layer of anastomosis.

In Figure 6 the posterior layer of silk has been tied to the anterior layer of catgut, but was first tied on itself to prevent any possibility of purse-string action. The anterior row of mattress sutures has been started. This layer is always started at the corner so as to invert the knot and is left long to be used as a traction suture. The mattress sutures must be *narrow* in order not to strangulate too much tissue.

Figure 7 shows the anterior row of mattress sutures completed with the two corner ones left long. The average anterior layer would contain 6 or 7 sutures, but only 4 are shown here for the sake of clarity.

Figure 8 shows the method used to get exposure to the mesenteric border. The end of one of the

Fig 16 This drawing illustrates our method of performing an end-to-side anastomosis aseptically. From this point, the operation is done in the same manner as it is done in the end-to-end procedure.

two mattress sutures which have been left long is carried through the rent in the mesentery and by applying gentle traction the bowel is turned up side down as shown in Figure 9. Figure 9 also shows the posterior line of mattress sutures partially laid. Two more would ordinarily be laid where the posterior layer of silk is still showing. We always make a point to put one suture right at the mesenteric border to insure good coaptation at this point as better illustrated in Figure 10 where the suture has not yet been tied. Figure 11 shows the bowel turned back into normal position with the external layer of mattress sutures completed. The mesentery is treated in one of two manners. Usually it is closed by direct coaptation care being used to close the triangular space in the exact position it was before it was divided. Sometimes the mesentery is overlapped as suggested by the Mayos (1). The rent in the mesentery is closed by a very carefully placed continuous suture of silk shown beginning in Figure 11. The closure of the small triangular mesenteric space on the opposite side is illustrated by Figure 12. It will be noted that the eye instead of the point of the needle is used for sewing to prevent damage to the mesenteric vessels.

Figures 13, 14, and 15 show the technique of performing a lateral anastomosis aseptically with the same instrument. Figure 13 shows the bowel brought together with the portion to be resected bulging through the blades of the clamp. In Figure 14 the posterior layer of silk has been laid and tied and the bowel wall has been cut away with cautery on one side and is shown in the process of excision on the opposite side. Figure 15 shows the method of laying the anterior row over both clamps. From this point on the anastomosis is completed in exactly the same manner as shown for the end to-end anastomosis, the final layer in each instance being a row of mattress sutures. Access to the posterior wall can be gained in the same manner also. About the only situation in which this operation is not feasible is when one encounters a very narrow terminal ileum making resection of a portion of the bowel wall dangerous because of the consequent further narrowing of its lumen. In this case we still use the old open method of anastomosis.

Figure 16 shows the same method applied to an end-to-side anastomosis. The posterior layer of silk has been laid and tied and the segment of the bowel wall to be used for the lumen of the anastomosis is shown in the process of excision. From this point onward the operation is done in exactly the same manner as previously shown in the technique for end to end anastomosis.

We feel that this clamp has certain very definite advantages over the previous instruments used for this purpose. It has a very narrow blade which therefore crushes very little tissue and consequently produces a very narrow cuff, thereby obviating the liability of diaphragm formation which has been one of the dangers in all of the older methods. In spite of this narrow blade, its strength and longitudinal grooves, together with the fact that it crushes evenly throughout its length, prevents any possibility of its slipping off and thereby soiling the field of operation. The fact that the handles are adjustable to right angles and the blades very short allows the instrument to be used in deep positions such as low in the pelvis where it would be impossible to work with any other type of instrument. Because of this fact a good many patients have been saved from a complete abdominoperineal operation. It is so simple and easy to handle that it saves a great deal of time, which is particularly important in this type of operation. It makes it easy to do aseptic end-to-end, lateral and end-to-side anastomoses. We have used a somewhat larger model of the same clamp for stomach resections using the same closed aseptic technique. However we had one case of severe hemorrhage and therefore, are somewhat doubtful as to the wisdom of using the instrument for this operation since it is impossible properly to control the large vessels in the stomach wall when sewing more or less blindly. We have found it quite useful for the inversion of the duodenum, however, because it destroys so little tissue and is easy to work with down in this more or less inaccessible region. The Parker Kerr method of inversion is used and reinforced with a layer of mattress sutures.

THE MODERN TECHNIQUE OF SUBTOTAL THYROIDECTOMY

JOSEPH L. DE COURCY, M D, F.A.C.S., Cincinnati, Ohio

IT is my purpose here to gather together into a synthesis the complete ensemble of pre-operative, operative, and postoperative treatment that has raised thyroidectomy from the status of a terrifying surgical specter to that of a safe and almost bloodless procedure with a mortality of less than one-fourth of 1 per cent in the hands of experienced surgeons, and a procedure having to its credit the restoration to health and usefulness of many thousands of unhappy toxic goiter patients.

I should like to stress what seems to me the importance of encouraging a greater number of general surgeons in localities remote from special thyroid clinics fitting themselves to carry out the technique of this modern operation. It will always be true that large clinics specializing in the surgical treatment of goiter are indispensable in this age of terrific nervous wear and tear, and that these centers can furnish the best care to patients able to remain indefinitely in the neighborhood for observation and treatment until cure is complete (often a long, slow process). The fact remains, however, that a substantial number of patients have to travel a long distance to reach one of these goiter centers, and that, for economic reasons, they can remain under the observation of the clinic for but a limited time. Large numbers of these patients must, far too soon, return to their own community and to the care of a clinician who has not the specialized understanding and experience of these cases.

How little the word of a thyrotoxic patient is worth in response to follow-up letters from the clinic, has been emphasized by Miller. His answer will be no true index to his degree of recovery. Such a patient will say he feels fine, though his pulse may be running wild as he writes. All these patients require the frequent examination of one who understands thyroid behavior and can determine to what degree the operation has been a success. Was sufficient thyroid tissue removed? Was too much tissue removed? Is further operation necessary? Or is the patient now a hypothyroid? Does he require thyroid extract? To answer these and other similar questions the presence on the spot of the surgeon who did the

operation is highly desirable. It may even be the determining factor in the patient's complete recovery.

It is unfortunately true that the great mass of the medical profession has a very imperfect conception of the requirements of these patients. The importance of correct postoperative care is so great that, if the operation and its follow-up treatment can be in the hands of one and the same surgeon for months or years, the advantage to the patient is immeasurable. It is possible for any surgeon of wide general experience to establish a competent thyroidectomy technique and to carry it out with an absolute precision which eliminates the risk of unexpected complications. It is the surgeon of this class that I have in mind in presenting this paper.

PRE-OPERATIVE PREPARATION

One should never be in a hurry about operating upon a thyrotoxic patient. The first prerequisite is rest of mind and body. In most of these cases the patient has been suffering for months or years with a sense of inability to bear the burdens that life presents. The mind has been in a state of worry, the body in a state of tension. The nerves and heart have reacted unfavorably.

If the case is one of only moderate hyperthyroidism, the patient may be allowed to sit up in a chair for a part of each day and even to take short walks about the hospital or its grounds. In more severe cases the patient is put to bed and kept there strictly for several weeks. In any case, the patient must be in the hands of cheerful and understanding physicians and nurses, who are equipped to maintain morale and to minimize the tendency to worry about domestic, financial, or other troubles. The patient's confidence must be gained and his fears with reference to the operation allayed. The hyperthyroid patient is always a hypersensitive individual and has a capacity for suffering that is absent from those who are built on a more phlegmatic pattern.

The diet must be carefully chosen to provide approximately 5000 calories per day. This high caloric diet must consist of materials easily digested and should contain a large amount of sugar to insure a good storage of liver glycogen. Candy

may be permitted *ad libitum*, unless there are diabetic complications. Meats are not prohibited, but must not be given in too large amounts. Fluids are given in large quantities, up to 3 to 4 liters a day. If edema appears due to the cardiac conditions, fluid is decreased until the heart function shows signs of becoming normal again. In rare cases hypodermoclysis may have to be employed if there is intolerance of fluids by mouth.

Most important among medical measures is the administration of Lugol's solution for 2 to 4 weeks previous to operation. It is now some 15 years since Plummer of the Mayo Clinic introduced the use of this compound iodine solution (free iodine 5 per cent, potassium iodide 10 per cent in 100 cubic centimeters of water) in treatment of hyperthyroidism. This has the effect of causing rapid involution of the hyperplasia and of reducing the goiter to a colloidal state, in part at least, thus making its removal easier and permitting greater thoroughness in operation. Its use has lessened the hazards of operation to a marked degree and has been one of the most important factors in eliminating the two to several stage operation formerly in almost universal use.

At the De Courcy Clinic all goiter patients, as a matter of routine, receive 10 minims of Lugol's solution 3 times a day for 2 to 4 weeks previous to operation, the time depending on the degree of clinical improvement observed and on the changes occurring in the gland itself as checked by metabolic readings. The immediate effects consist of relaxation of nervous tension, a control of toxic symptoms, a fall in the basal metabolic rate of 2 to 4 points daily, and increase of appetite and a sounder sleep. This improvement is only temporary, however, and must not be taken to indicate that operation has become unnecessary.

Boothby has shown in a series of graphs that the introduction of iodine previous to operation caused a drop in operative mortality from between 3 and 4 per cent to less than 1 per cent and reduced the number of stage operations from 50 per cent to 2 per cent, permitting subtotal thyroidectomy in a single operation to take their place.

The earliest moment of full iodization is not necessarily the optimum time to operate. The time of operation should be chosen on the basis of the patient's condition and not on any basis of a fixed time after the beginning of iodine administration.

For toxic thyroid patients, who exhibit severe signs of heart failure, thorough digitalization should be brought about. Patients are put to bed and given from 5 to 10 drops of tincture of digitalis 3 times a day according to the degree of

decompensation. This is usually discontinued 5 days before the operation. In these cases, if edema is present, fluids are restricted to not over 1 liter a day. In very severe cases preliminary blood transfusion may be a necessary prophylactic measure. Sedation must of course be administered to patients in a state of great nervous excitement. The preoperative use of iodine is doubly important in cases of patients in whom a psychosis is present, in view of the danger of its exacerbation immediately after operation.

The ideal time for operation is found when nervousness is overcome, weight either stationary or gaining, pulse rate below 100, and the basal metabolic rate less than plus 40. I feel that no operation should ever be undertaken while weight is still falling since this means that catabolism overbalances anabolism and that consequently the thyroid function is too active for surgery.

In extremely toxic cases, or those patients in whom there is an excessively large goiter, it is sometimes still necessary to do a two stage operation, especially if the patients do not improve under iodine medication.

IMMEDIATE PRE OPERATIVE PREPARATION

The patient receives a soapsuds enema on the evening before operation. By mouth 30 minims of Lugol's solution is administered at this time. Appropriate sedation is given to secure a good night's rest. The following morning $\frac{1}{2}$ to $\frac{1}{4}$ gram of morphine is given 1 hour before operation. This enables the patient to approach the time of operation in the perfect peace of mind that is indispensable for the best operative results. Rather liberal premedication is desirable to lessen the inevitable nervousness and excitement incident to the approaching ordeal in this type of patient.

ANESTHESIA

Since 1920 approximately 9,200 goiter operations have been performed at the De Courcy Clinic under various methods of anesthesia. After a thorough trial of local anesthesia in 500 cases and of ether and a number of other methods, we have given all of these up in favor of nitrous oxide and oxygen which we began to use in 1923. Among its many advantages are the rapidity with which it takes effect, the promptness of recovery, and the easy regulation of dosage. With this type of anesthesia it is possible to deepen or lighten at will the degree of narcosis. Postoperative vomiting is infrequent and postoperative hemorrhage very rarely occurs.

The chief disadvantage of local anesthesia which is favored by many on account of its lack

Fig 1 Lower left, incision through skin and platysma
 Fig. 2 Lower right, longitudinal incision of fascia
 Fig 3 Above, freeing of gland from overlying structures

of toxicity, lies in the fact that these patients, being very nervous and excitable, often cannot tolerate an operation done while they are in a conscious state. In addition, local anesthesia has often been found inadequate during the stage at which the lateral lobes of the gland are elevated, and the surgeon on the whole has less freedom for rapid manipulation.

Because of the frequency with which a damaged myocardium is present in these operations, an efficient airway is a *sine qua non* for their execution. This is best secured by the free flow of oxygen obtainable under nitrous oxide combined with oxygen, which can be given in any proportion desired and varied from one moment to another according to need.

OPERATIVE TECHNIQUE

1 With the patient in the recumbent position, the incision is usually made in one of the lower creases of the neck. It should, however, not be so low as to sag down at a later time below the natural lowest skin crease. Too much curvature is to be avoided. The knife should be drawn across the neck with an arm motion, which does not bend the hand at the wrist, so as to prevent a feathering of the skin margins and thus to permit a better connective result. The incision should be carried through the closely adherent platysma to facilitate blunt dissection (Fig 1).

Small bleeders or oozing spots in the skin flap are grasped with small hemostats and coagulated. This eliminates ligation which frequently becomes

Fig 4 Ligation of superior pole

noticeable later because of cystic accumulation about the catgut.

Care should be taken to cut in the fascial plane between the platysma and fascia on the anterior surface of the ribbon muscles. In order to avoid severing the cutaneous nerves, which would result in later numbness and in paresthesias that some times occur from the chin downward, the skin flap should not be raised laterally more than just enough to make a V between the lateral ends of the incision and the highest point of the midline.

2 It is seldom necessary or desirable to sever the ribbon muscles but in the hands of a less experienced operator such a division may for a time be the safer course until greater proficiency is gained. In such case the division should be made high up and as near the larynx as possible in order to reduce the possible damage to the nerve supply of the upper portion of the muscle. After experience has been gained sufficient visualization is obtainable if the longitudinal incision of the fascia is carried well up over the laryngeal cartilage (Fig 2). Previous to the days of iodine zation, it was difficult to raise the hyperplastic gland and therefore necessary to divide the ribbon muscles.

Occasionally today we divide the muscles in very large substernal goiters or in those which because they are iodine fast, fail to undergo colloid involution. These indications are however relatively rare.

3 Blunt dissection over the gland with the fingers facilitates delivery. No attempt is made to go around the gland, because in doing this there is danger of tearing the lateral vein and also of traumatizing the recurrent laryngeal nerve (Fig 3).

A definite strip must be left on each side toward the back of the gland, in order to preserve intact the parathyroids and the recurrent laryngeal nerve. If by chance a parathyroid is damaged the accidentally dissected gland should be immediately reimplanted. One should avoid the removal of any fat like processes, since the exact position of the parathyroids is not always predictable. In the event of injury to the laryngeal nerve, revealed by a change in the type of breathing the nerve should be repaired at once if it is cut, it must be sutured. If a clamp is making pressure upon it, it must be removed.

4 Elevation of the right lobe can usually be accomplished to a point sufficient to apply the traction forceps by use of a mouse tooth tissue forceps. After applying this and elevating the lobe with the traction forceps, the sternothyroid muscle which is adherent to the side of the gland, is wiped down with a piece of gauze as the lobe is being elevated.

5 The superior pole is next dissected free and a double strand of No 2 chromic catgut passed above the pole and tied thus the superior artery is secured. Before the carrier is passed around the pole, the latter is elevated by passing the finger underneath and raising it (Fig 4).

Because of the close proximity of the superior laryngeal nerve, some surgeons feel that it is necessary to dissect out the superior artery and tie it under direct vision.

In doing a number of dissections on the cadaver I have found this to be unnecessary and undesirable for two reasons. First the artery frequently divides some distance above its entrance into the gland and there is some danger of injuring the nerve because of the added trauma. Second because of the poor exposure at this point retraction of the artery frequently occurs after the clamp is applied and makes ligation not only difficult but also hazardous, besides encouraging slipping of the knot with primary or secondary hemorrhage.

If the finger is passed under the superior pole and the pole is raised the carrier is passed only around the vessels and there is no danger to the nerve or the trachea. In the examination of 10 cadavers ligated in this manner with subsequent inspection the superior laryngeal nerve was not included in the ligation once.

Fig 5 Stripping right lobe across trachea

Fig 6 Elevation of left lobe by traction upon right lobe after trachea has been dissected free

6 After elevation of the right lobe and ligation of the superior artery, the superior pole is incised with a knife proximal to the ligature. This incision facilitates further elevation of the gland and permits a more even dissection, thereby lessening the chance of leaving too much glandular tissue at the superior pole, which would favor a recurrence at this site.

Straight mouse-toothed hemostats are applied along the side of the gland at right angles to the trachea. These hemostats clamp the branches of the inferior artery and veins as they penetrate the gland. The trunk of the inferior artery is not exposed. I still feel that the ligation of this trunk lessens or entirely destroys the blood supply to the parathyroid bodies and encourages tetany.

The amount of gland to leave is always a controversial question. It is better to remove too much than too little, because the remaining portion will usually hypertrophy to a point sufficient to maintain normal body metabolism. As a rule, in my opinion, not less than four-fifths of the gland should be removed if thyrotoxicosis is to be relieved, but, of course, the amount varies with the individual case. A practical way is to

place the hemostats so that they will lie on a plane with the anterior surface of the trachea if the gland is elevated at the time the clamps are placed.

7. The right lobe is then dissected from without inward until the trachea is reached. The surgeon then usually disregards the right lobe and proceeds to dissect the left lobe, leaving the trachea until the last.

Instead of doing this, I continue the dissection of the right lobe right across the trachea and slightly under the left lobe. When the trachea is reached, a little traction discloses a line of cleavage, and dissection of the isthmus is greatly facilitated without damage to the trachea (Fig 5).

8 After the trachea is crossed, traction upon the right lobe and isthmus automatically lifts the left lobe from its bed and in this way eliminates the trauma which is sometimes required during the effort to raise the left lobe. By this method it is usually possible to elevate both lobes with thumb forceps only (Fig 6).

9 After subtotal thyroidectomy the clamped vessels are ligated individually with No. 2 chromic gut. If it is thought necessary, some of the sutures may be anchored. No attempt is made to close

Fig 7 Suture of sternothyroid muscle to pretracheal fascia

over the anatomical capsule of the gland. Instead the sternothyroid muscle is sutured on either side to the pretracheal fascia with No. 6 plain catgut (Fig. 7). This muscle not only acts as a hemostatic agent over any seepage from the gland surface but prevents any overlying adhesions to the gland itself as well.

Since we have been doing this we have eliminated drainage in all but the very exceptional case in which a large cavity remains after removal of the substernal goiter.

In our last series of 2,000 cases we have not drained thyroidectomy wounds with very few exceptions (less than 1 per cent) and have thereby lessened the convalescent period very perceptibly.

10. The ribbon muscles are next sutured vertically and the skin closed with clips, to be removed in 72 hours (Figs. 8, 9, 10).

The principal accidents to be guarded against are hemorrhage, injuries to the parathyroids or to the recurrent laryngeal nerve, collapse of the trachea and air embolism through the large veins of the neck. If a scrupulous technique is observed none of these is likely to occur. In the event of a collapse of the trachea tracheotomy must be done instantly.

Fig. 8 Above sternothyroid muscle sutured to pretracheal fascia.

Fig. 9 Lower left longitudinal incision of fascia sutured.

Fig. 10 Lower right skin incision closed.

POSTOPERATIVE CARE

The postoperative treatment of goiter cases has been tremendously simplified since the introduction of preoperative iodine treatment. In most cases there is immediate improvement consisting of relief of tachycardia, muscular tremor, restlessness and fever.

The patient is put to bed in a comfortable position and watched closely for complications. Lugol's solution is as useful after operation as it was before. In the average case the patient receives 10 minims every 8 hours, beginning as soon as he is back in bed. In all toxic cases, however, he is given 30 minims by rectum upon his return to bed and this is repeated 8 hours later. In rare cases a third large dose is given. Fluid is administered subcutaneously and may be taken by mouth if there is no vomiting. Application of warmth and administration of sedatives are necessary. Oxygen may be required and the oxygen tent should be in readiness for such emergency.

In cases of extreme prostration transfusion may be necessary. In the event of a thyroid crisis—now happily a rare occurrence since the introduction of Lugol's solution pre-operatively—iodine

and quinine hydrobromide are immediately given with intravenous glucose, oxygen, and refrigeration. If signs of tetany occur, parathyroid Collip extract and calcium lactate should be in readiness. In the average patient, however, none of these emergencies arise and the patient makes an uneventful recovery.

AMOUNT OF GLAND TO REMOVE

The question of how much thyroid tissue to remove is far from being purely academic.

If too little is removed, the result is a continuance or recurrence of thyrotoxicosis. Many patients will never be persuaded to undergo a second operation, even though it be greatly needed. In such cases it is important to do a radical operation from the start. If, through fear of giving rise to myxedema, too little gland is removed, it may be impossible ever to persuade the patient to return again. This should impress upon us the realization that an ineffective operation means a defeat to surgery.

On the other hand, the removal of too much thyroid tissue invites myxedema, which may involve personality changes. The general consensus is that too much should be removed rather than too little, since the probability is that the gland will grow again to some extent and will thereby replace lost tissue, and thus myxedematous changes will be prevented.

Lahey, who has given close attention to this problem, concludes that a correct decision can be made on the basis of the degree of involution that has been brought about before operation by Lugol's solution. In the case of patients on whom this iodine involution is of high degree, as judged by gross appearance (pale, edematous tissue), he would remove relatively less tissue, in order not to impair the reproductive ability of what is left, which is now small. In patients in whom involution is of low degree, with a brownish red and cellular appearance of the tissue, he would remove a large quantity, lest its reproduction be too easy, resulting in return of excessive thyroid activity.

According to Pool and Garlock, there seems little doubt that the occasional thyroid surgeon, not a specialist, will have a high recurrence rate, because of inadequate removal of this gland. He is afraid of injuring the parathyroids and the

laryngeal nerve, and in addition he has not yet developed a standard procedure. He may therefore expect many recurrences before he has learned to operate efficiently and adequately in this disease. Pool and Garlock themselves report a recurrence rate of 93 per cent in a series of 171 primary resections.

My own conviction is that it is much better to remove too much than too little of the thyroid gland, since we have very good means now of combating hypothyroidism by thyroid feeding, whereas hyperthyroidism can thus far be overcome only by surgical means. As already pointed out, the patient is with difficulty persuaded to return for repetition of a procedure that has already failed to bring relief.

SUMMARY

1. It was chiefly the arrival of the artery clamp that made possible the modern surgical treatment of goiter.
2. General surgeons should equip themselves more generally to perform this important operation.
3. The surgical technique of subtotal thyroidectomy is presented.
4. It is safer to remove too much than too little of the hyperplastic thyroid gland.

A STUDY AND END-RESULT REPORT OF SEVENTY ARTHROPLASTIES AND RECONSTRUCTION OPERATIONS ON THE HIP JOINT

HALFORD HALLOCK, M D, F A C S New York New York

A STUDY has been made of all the arthroplasties and reconstruction operations of the hip joint that have been performed at the New York Orthopedic Dispensary and Hospital from August 1916 to October, 1934.

Seventy five operations have been done on 71 patients. In 2 of the patients a second mobilizing procedure was done on the same hip and in 2, bilateral operations were performed but at different times.

Five patients were followed for less than 1 year for reasons outside of our control. This leaves 70 operations in which there has been a follow up examination of 1 year or more. The longest follow up time was 12 years and the average was 3.5 expressed as case years, the average time was 4.

No selection of patients for operation was made, provided that there were present severe enough symptoms to warrant major surgery and that the cause of the disability was such as to make a mobilizing procedure proper. In many the degree of joint damage was staggering such as complete destruction of the head and neck and dislocation of the femoral shaft upon the ilium or tremendous overgrowth and deformity of the head with degeneration of cartilage and obliteration of the joint space. By operation it was hoped to give these distressed patients stable hips that were free from pain and that had adequate ranges of mobility.

ETIOLOGY

The cases were divided according to history and x ray findings into the following groups: osteo-arthritis, 18 cases, osteo arthritis following trauma without fracture 2, osteo-arthritis following fracture, 3, osteo-arthritis following non specific synovitis, 1, rheumatoid arthritis, 2, infectious arthritis, 2, arthritis or ankylosis due to the gonococcus, 3, residual adolescent slipped epiphysis, 6, residual coxa plana or magna 8, fibrous ankylosis following operative procedures 3, stabilization of old congenital dislocation of the hip

1, ununited fracture of the femoral neck, 1, residual suppurative arthritis, 20 a total of 70 cases.

The 3 cases of osteo-arthritis resulting from fracture followed a compression fracture of the upper portion of the femoral head, a fracture of the acetabulum with posterior dislocation of the hip and a fracture of the neck with malunion.

The 2 cases of infectious arthritis followed respectively scarlet fever and phlebitis. Suppuration did not occur.

The gonorrheal cases included 2 with fibrous and 1 with bony ankylosis.

The 3 cases of fibrous ankylosis following operations resulted from open reductions 2 for congenital dislocation of the hip and 1 for adolescent slipped epiphysis.

The 20 cases of residual suppurative arthritis are from the standpoint of therapy a formidable group. Half of them presented dislocation following destruction of the femoral head and neck, and 3 had bony ankylosis. One case thought to be pyogenic in origin was proved later by microscopical section to be tuberculous. In this patient fusion has been obtained and an excellent result with complete subsidence of the disease.

AGE AND DURATION OF SYMPTOMS

The ages of the patients at operation varied from 18 months to 66 years. The average was 29 years.

The duration of symptoms prior to operation ranged from 18 months to 26 years and averaged 6 years.

SYMPTOMATOLOGY

The patients complained of pain, limitation of motion, instability, deformity and shortening.

Pain. Fourteen patients had no pain before operation. 6 of these suffered dislocations. 1 was only slightly over 2 years of age and had almost a dislocation (residual suppurative arthritis), 4 had bony ankylosis and 3 had fibrous ankylosis that allowed slight or no motion at all.

Four patients had pain estimated as 1 plus in seventy (scale 0 to 4 plus), 12 2 plus, 26 3 plus and 10 4 plus. No pre operative note was made in 4. The average amount of pain was 2 plus.

Limitation of motion In order to express completely and simply the entire range of mobility present in any given hip joint, the index of function was employed that was described by Ferguson and Howorth.¹ To obtain this index, the degrees of motion present in each arc of mobility are multiplied by a suitable factor, the size of which depends upon the relative importance of that particular arc for function of the hip as a whole. The products are added and the sum is the index of function. The factors chosen were: for flexion 0.4, for extension 0.1, for abduction 0.4, for adduction 0.2, for internal rotation 0.2, for external rotation 0.1. The normal hip has an index of from 90 to 110. Table I is an illustration.

TABLE I —EXAMPLE

Arc of motion	Degree of motion	Factor	Product
Flexion	145	0.4	58
Extension	10	0.1	1
Abduction	45	0.4	18
Adduction	30	0.2	6
Internal rotation	30	0.2	6
External rotation	60	0.1	6
Index of function			95

EXPRESSED IN GENERAL TERMS

	Degrees
Hypermobile	Over 110
Normal	90-110
Good	60-90
Fair	50-60
Indifferent	40-50
Poor	30-40
Bad	Under 30

Excluding for reason of simplicity, the patients with dislocation (13, 12 before operation and 1 after), the index of function before operation ranged from 0 to 57 and averaged 21. Expressed in general terms, the indices of motion were distributed as shown in Table II.

TABLE II

	Cases
Normal (Index of 90-100)	0
Good (Index of 60-90)	0
Fair (Index of 30-60)	22
Poor (Index of 1-30)	28
No motion (0)	7

Instability Twelve patients presented dislocations before operation. Ten of these were the result of suppurative arthritis, 1 was a fracture dislocation and 1 was a congenital dislocation complicated by polyomyelitis.

Deformity Some degree of deformity was the rule. Flexion deformity was noted before opera-

tion in 52 instances and lateral deformity, usually adduction, in 37. Severe flexion deformity (over 35°) occurred 14 times and pronounced adduction (over 10 degrees) 15 times.

Shortening Shortening was noted before operation in 51 patients and the average amount was 0.9 inch. Eighteen of these were suppurative cases and their average shortening was 1.5 inches. The average shortening in the remainder of the patients was 0.4 inch.

In one or two instances, due to an accompanying pathological process in the opposite hip, the shortening was present on the side not operated upon.

THE OPERATIVE PROCEDURES

The operative procedures varied a great deal. This variation in technique was due in part to the fact that the operations were performed by 8 or 10 different surgeons, but in general the type of technique was determined by the conditions found upon exposure of the joint.

All of the operations were of a plastic nature and can be called arthroplasties, but, in the sense that an arthroplasty attempts to provide a newly constructed joint with as near the normal form, and structure as possible and with interposed tissue or artificial membrane, most of the procedures must be termed reconstructions. The two terms, however, are used in this study interchangeably.

When the femoral head was enlarged, overgrown, or deformed, it was the custom either to trim and shape it, thus reducing it in size and sometimes depth, or to remove it completely, thus allowing the rounded end of the neck to engage in the acetabulum. When the femoral head had been destroyed, the end of the neck was reshaped and placed in the acetabulum and the trochanter was usually transplanted to a lower level on the shaft, or was split out laterally to increase the leverage of the abductor muscles and to increase the bearing surface of the superior aspect of the neck. When the femoral neck had been completely or subtotally destroyed, a so called bifurcation operation was used in which the upper end of the femoral shaft was split longitudinally, the medial half reduced into the acetabulum and the outer or trochanteric portion green-stick fractured outward and held in position by bone fragments placed in the cleft.

When the acetabulum was shallow, it was made deeper by curetting or gouging, sometimes to bone. Osteophytic ridges on the margins of the acetabulum were removed.

Usually no interposed tissue was considered necessary but Baer's membrane was used twice,

Fig 1 C W Absorption and sequestration of epiphyseal bone following extensive partial resection of the femoral head in a case of bony ankylosis following gonorrheal infection in a girl aged 16 years a Immediately after operation After separation from the acetabulum the head was reduced in size to the diameter of the neck A double layer of fascia lata was interposed Motion was begun in 2 weeks b Four months after operation Aseptic sequestration has occurred superiorly in the head and absorption inferiorly c Three years after operation The sequestrum was removed 8 months after the arthroplasty Pre operative pain 0 3 years after operation 2 plus Pre operative index of function 0 3 years after operation 26

a single layer of fascia lata 4 times, a double layer 4, and a pedicle fibrous tissue flap once

In 1 patient (with compression fracture of the head with resultant osteo arthritis) the operation consisted only of a removal of loose bodies from the acetabulum and a covering of the head with a single layer of fascia lata In 1 of the cases of residual suppurative arthritis in which the head and some of the neck had been destroyed a shelf of bone was turned down from the ilium to overlie the reduced and reshaped upper end of the femoral shaft In a case of bony ankylosis following suppurative arthritis, the end of the femur was chiseled free and made to articulate beneath a narrow shelf or ridge left on the ilium In a patient who had a painful fibrous ankylosis following gonorrheal infection, the proximal portion of the femoral head was inadvertently left in the acetabulum The neck was covered with fascia and reduced The remnant of head became fused to the acetabulum, but motion was retained between the head and the neck and this has turned out to be one of the best results

The femoral head was trimmed reshaped, reduced in size and sometimes depth in 24 instances it was completely or subtotally ($\frac{3}{4}$ or more) removed in 25 The acetabulum was curetted deepened "excavated" or gouged in 21 patients In

Fig 2 V V Aseptic sequestration of the femoral head following extensive partial resection at arthroplasty in a young woman aged 24 years with chronic infectious arthritis of the hips The head was reduced to one half its size and the trochanter was transplanted Motion was started at 5 weeks Sequestration of epiphyseal bone occurred but the sequestrum eventually reunited to the neck a Six months after operation The line of sequestration is visible b Three years after operation The sequestrum is present and is of increased density c Six years after operation The sequestrum has reunited to the neck Pre operative pain 3 plus 6 years after operation 1 plus Pre operative index of function 5 6 years after operation 8

2 of these the records state that bone was exposed after the gouging or curetting and in 1 a new acetabulum made out of solid bone The greater trochanter was transplanted or split out 51 times

Postoperative treatment Usually plaster immobilization was maintained for from 3 to 6 weeks after operation This was done chiefly to allow the transplanted trochanter to become firmly united before motion was begun In 9 patients for reasons not stated in the histories plaster casts were kept on for several months Seven of these were patients with residual suppurative arthritis accompanied by dislocation and in whom the danger of redislocation was probably great

The average time that motion was begun after operation was 6.5 weeks In 7 motion was started within 2 weeks The average pre operative index of these 7 was 10, and at follow up 24 All the gain occurred in 4

Physiotherapy was continued for as long as possible after the patient had left the ward Its duration was of course subject to great variation

COMPLICATIONS

Fortunately there were not many complications Four deep wound infections occurred Two of these were in residual suppurative cases In one of the latter *Staphylococcus aureus* was cultured at the time of operation The original infection in this case had occurred 8 years prior to

Fig 3 M C Sequestration and absorption of femoral head following partial resection in an arthroplasty on a girl aged 8 years who for 1 year had had a stiff hip after open reduction for congenital dislocation. The head was reshaped and the upper part of the acetabulum was enlarged. A double layer of fascia lata was interposed. The trochanter was not transplanted. Motion was begun in 2 weeks. a, Immediately after operation. b, One month after operation. The head has separated from the neck. c, Seven months after operation. The head is absorbing and the neck and shaft have subluxated. d, Fifteen months after operation. Further absorption of the head has occurred. The femur has subluxated. Pre-operative pain, 0, 3 years after operation, 0. Pre-operative index of function, 0, 3 years after operation, 32.

arthroplasty and all sinuses had been closed for 5 years. Four patients developed sinuses. Two of these occurred in the 2 residual suppurative cases with wound infections. Other complications were massive skin flap necrosis, 2 cases, stitch abscess, 1, superficial wound infection, 1, hematoma, 1, non-fatal pulmonary embolus, 1.

SUBSEQUENT OPERATIONS

Eight patients subsequently had hip fusion operations because of failure of the arthroplasty. In 2 patients a transplantation of the trochanter to increase abductor muscle leverage was done, in 1 a re-attachment of a trochanter that had pulled loose, in 1 a shelf stabilization for failure to achieve stability following reconstruction for residual suppurative arthritis with dislocation, and in 1 removal of an aseptic sequestrum from the femoral head. In addition, a few hip stretchings or mobilizations under anesthesia were performed.

RESULTS

Mortality. There were no operative deaths but 2 patients have subsequently died: 1 of carcinoma of the ovaries 5 years after arthroplasty, and 1 of nephritis 6 years after arthroplasty.

Pain. The average amount of pain before operation was 2 plus, at follow-up examination, 1 plus. Twenty-six patients had no pain after operation, 21, 1 plus, 11, 2 plus, 5, 3 plus, and 3, 4 plus. No note was made in 4. Fourteen of the patients before operation had no pain. At follow-up, 10

of these were still free of pain, 2 had 1 plus and 1 had 2 plus pain. No note was made in 1. Fifty-two of the patients before operation had painful hips. At follow-up, 14 of these were free from pain and 36 were still painful (no note in 2). Of the 39 that were painful after arthroplasty, 26 were less painful than before the operation, 5 were more painful and 8 were the same (Table III).

TABLE III —RESULTS AS TO PAIN

Average pain pre-operatively	2 plus 1 plus	
Average pain at follow-up	Before operation cases	At follow-up cases
No pain	14	26
1 plus	4	21
2 plus	12	11
3 plus	26	5
4 plus	10	3
No note	4	4
	70	70

Results: no pain, 14, pain, 36, no note, 2		
Hips painful after operation		39
Less painful than before operation, 26, the same, 8, more painful, 5		

Mobility. The average index of function before operation was 21, at follow-up examination 18, all patients with dislocations (13) being excluded.

Expressed in general terms, the follow-up indices after operation were distributed as follows:

Fig 4 L. C. Arthroplasty for residual suppurative arthritis with dislocation in child aged 1½ years. At operation the acetabulum was deepened exposing bone. The end of the femoral neck was trimmed. The trochanter was braced outward from the neck ¼ inch and supported in position by a bone transplant. Motion was begun in 6 weeks. The series of roentgenograms shows the joint changes that occurred over a period of 5 years. Before operation the patient was free from pain but dislocation

was present and the index of function was 90. Six years after operation she had no pain the index was 60 and reduction of the dislocation had been maintained. a The pre-operative condition b Two months after operation c Six months after operation d Fourteen months after operation e Absorption is beginning at the articular surface of the neck f Three years after operation g Five years after operation. Absorption is more marked.

normal (index 90-100), 0, good (index of 60-90), 2 fair (index of 30-60), 11, poor (1-30), 34, no motion (0) 0, no note, 1

The index of function was improved in 29 per cent (16 patients) and the average gain was 22, it was lowered in 39 per cent (72 patients) the average loss being 20, it was changed by less than 5 or not affected in 32 per cent (18 patients).

Comparison with the pre operative condition is made in Table IV.

TABLE IV.—RESULTS AS TO FUNCTION
DISLOCATED CASES EXCLUDED

Average index before operation	21
Average index at follow up	18
Normal motion (90-100)	0
Good motion (60-90)	0
Fair motion (30-60)	22
Poor motion (1-30)	28
No motion (0)	7
No note	1
	57
	57
Index improved	16
Index lowered	22
Index unaffected	18
Average gain in index	22
Average loss in index	20

Thirty five patients had pre operative indices of from 0 to 30, and 22 of from 30 to 60. The aver-

age follow up index for the former group was 11 and for the latter 30. These figures indicate that in general those patients with fair ranges of mobility before operation retained fair motion after and that those with poor mobility finished with little motion.

Relation of pain to mobility after operation. Absence of motion by bony fusion or tight fibrous ankylosis occurred more often in the hips that at follow up examination were not painful (31 per cent of 26) than in those that were (3 per cent of 40). This indicates that absence of motion was probably a factor in the number of hips that were eventually free from pain after arthroplasty was performed.

Results as to pain and mobility in relation to etiological groups. The number of patients in most of the groups is so small that no conclusions can be drawn except in the divisions of osteo-arthritis and residual suppurative arthritis. In the former group of patients alleviation of average pain occurred (average before operation 3 plus after, 1 plus) but motion in general was somewhat decreased (average pre operative index, 28, post operative 23). In the latter group average pain was unaffected (average before operation ½ plus after ½ plus) and motion was generally lost (average pre operative index 20 patients with dislocations 40 postoperative 4 patients with dislocations 15).

Fig 5 R B Residual suppurative arthritis with dislocation in a girl aged 17 years. The original infection occurred at the age of 1 year. At operation, fibrous tissue was removed from the acetabulum, the trochanter was removed and transplanted, and the intertrochanteric portion of the femoral shaft was placed in the acetabulum. Motion was started at 7 weeks. The end-result was fusion of the joint. a, Before operation. b, Immediately after operation. c, Five years after operation.

Dislocation Dislocation was cured in 8 of the 12 patients that presented this complicating abnormality before operation. Four remained uncured. The average pre-operative index was 73 and at follow-up 37. Excluding the 4 patients with residual dislocations the average follow-up index was 27. A good deal of mobility was therefore sacrificed for stability. One patient (an osteo-arthritis) with no dislocation before operation suffered a dislocation several years after.

Deformity Flexion deformity after operation was recorded in 37 instances and lateral deformity in 38. Severe flexion deformity (over 35°) occurred 7 times (14 times before operation) and pronounced adduction deformity (over 10°) 3 times (15 times before operation). Three patients with less than 35 degrees of flexion deformity before, had more than 35 degrees after operation, and 2 patients with slight adduction deformity before had excessive adduction after.

Shortening Shortening was noted at follow-up examination in 26 patients and the average amount was 1.5 inches (0.9 inch before operation).

Results in those with bony ankylosis. Of the 4 patients who had bony ankylosis before operation, 3 from suppurative arthritis and 1 from gonorrhea, 3 presented bony ankylosis at follow-up and 1 (the neisserian infection) mobility with an index of 26. The last, however, had pain.

Effect of interposed tissue. As already stated some form of interposed tissue, usually fascia

Fig 6 H B Arthroplasty for residual gonorrheal arthritis in a male aged 29 years. It was intended at operation to remove the entire femoral head but the proximal portion was inadvertently left in the acetabulum and the pointed end of the neck was placed against it, but separated from it by a double layer of fascia. Motion was begun in 4 weeks. The remnant of head eventually became fused to the acetabulum, but a good range of motion without pain was preserved between the fused portion of head and the neck. a, The pre-operative condition. b, One month after operation. c, Two and one-half years after operation. Pre-operative pain, 1 plus, 3 years after operation, 0. Pre-operative index of function, 4, 3 years after operation, 56.

Fig 7 E F Arthroplasty in a woman aged 40 years for osteo-arthritis following an old coxa plana. The head was removed and the remodeled end of the neck was placed in the acetabulum. The trochanter was not transplanted and interposed tissue was not used. Motion was begun within a few days, but had to be discontinued because of the occurrence of several non-fatal pulmonary emboli. At 8½ weeks, the patient was walking with crutches. a, Before operation. Note the tremendous amount of structural deformity present. b, Three years after operation. Pre-operative pain, 4 plus, 3 years after operation, 1 plus. Pre-operative index of function, 32, 3 years after operation, 31.

lata, was employed in 11 patients whose average pre operative index was 10. Five gained in index by 26, 32, 28, 52, and 5, respectively, 2 lost by 14 and 36 and 4 were unaffected or changed by less than 5. The average postoperative index was 18.

Effect of the amount of bone removed from the femoral head. It has been observed by Albert Ferguson that it is not safe to remove more than one third of the circumference of the femoral head because absorption of the remaining portion will often occur, which may materially and probably adversely affect the end result (Figs. 1, 2, and 3). Therefore, if circumstances demand that more than that amount be resected, it is wiser to remove the head completely and to reshape the end of the neck for articulation with the acetabulum.

THE DEVELOPMENT OF A BETTER OPERATIVE TECHNIQUE

From a study of these cases certain principles of arthroplasty have been derived:

1. More than one third of the circumference of the femoral head must not be removed, if conditions demand the resection of more bone, the femoral head should be removed completely.

2. The remodeled head or neck should preferably be covered with a double layer of fascia lata.

3. The trochanter should not be transplanted at the time of the reconstructive procedure. It is left intact so that motion can be begun immediately (This does not apply to patients who have practically no femoral neck in which the trochanter, at the time of operation, must be removed or propped out in order to provide a femoral bearing surface to articulate with the acetabulum.)

4. Motion must be started immediately or within 2 or 3 days of operation and physiotherapy must be continued for many months after.

5. A proper selection of cases must be made, if good results are to be anticipated. Lazy or in different individuals or those with a low threshold value for pain are not good subjects for arthroplasty. Patients who have had ankyloses for years and consequently, have markedly atrophied muscles which cannot possibly function after mobilization of the joints, or those who present gross damage or tremendous deformity of structure, usually will not obtain good results.

Since October 1934 10 patients have been operated upon with these principles in mind. All have been examined a year or more after operation and the results have been most encouraging. The trochanter has been transplanted at a second operation in 1 patient because there was insufficient length of neck for a stable joint. One pa-

tient has sustained a dislocation following a severe and deep operative infection. The patients have good ranges of motion with a substantial gain in the index in every instance, and in general have decreased pain.

It must be borne in mind, however, that pronounced pain and limp may persist after a mobilizing operation. Before an arthroplasty is performed therefore the patient should thoroughly understand this fact and be willing to accept this possibility in order to obtain or preserve mobility. A fused hip, however in optimum position and in unilateral cases gives a beautiful end result, providing a painless, stable extremity, without marked limp, that can be relied upon for full use. Consequently, in many instances, hip fusion may be the operation of choice.

SUMMARY

1. A study of all the arthroplasties and reconstruction operations on the hip joint that have been performed at the New York Orthopedic Dispensary and Hospital from August, 1916 to October 1934 has been made.

2. The terms "arthroplasty" and "reconstruction" are used interchangeably in this study to denote a mobilizing procedure.

3. Seventy five operations have been done on 71 patients. Five cases for reasons outside of our control were followed for less than 1 year. This leaves 66 patients with 70 operations that have had a follow up examination of more than 1 year. The longest follow up time is 12 years and the average is 3.5 or 4 case years.

4. The average amount of pre operative pain was 2 plus (scale 0-4 plus) and the average amount at follow up was 1 plus.

5. The average functional index before operation was 21 and at follow up examination 18. The index was improved in 29 per cent with an average gain of 22. It was lowered in 39 per cent with an average loss of 20 and it was unaffected in 32 per cent.

6. Twelve patients presented pre operative dislocation. This was cured in 8 but at the sacrifice of a good deal of mobility. One patient who did not have a dislocation before operation had one 2 or 3 years later.

7. Certain principles of arthroplasty that have been derived from the study of these cases are stated. These have changed the technique of operation since 1934.

8. With these principles in mind much better results have been obtained in 10 patients that have been so operated upon and followed for more than 1 year.

THE USE OF LIVING SUTURES OF THE EXTERNAL OBLIQUE APONEUROSIS IN THE REPAIR OF INGUINAL HERNIAS IN ADULTS

J DEWEY BISGARD, M D , Omaha, Nebraska

IT IS the purpose of this article to report an operative technique for the repair of inguinal hernias and to propose the routine use of fascial sutures in the repair of inguinal hernias in adults

Several autoplactic operations have been reported. The original one was devised by McArthur and reported by him in 1901. He employed the Bassini principle of repair but used pedicled strips of the external oblique aponeurosis as sutures to approximate the conjoined and Poupart's ligaments and to reapproximate the cut edges of the external oblique aponeurosis. The technique here described differs from the McArthur operation in that it incorporates a detail which I believe contributes much security, particularly in the repair of that group of hernias which have inadequate but not totally deficient support in the superpubic portion of the inguinal triangle. These include direct and combined direct and indirect, or saddle bag, hernias in which the aponeurosis of the internal oblique inserts into the pubis or sufficiently low that it can be approximated to Poupart's ligament without much tension and also the indirect hernias which have lost their obliquity because the internal rings extend down to the pubis.

This detail consists of utilization of the triangular fascia, the ligamentum inguinale reflexum—Colles's ligament—to obturate completely the small triangular defect which is left between the pubic spine and the lowermost approximating stitch in the classical operations.

Although utilization of this band of fascia in repair has been referred to in the literature, it is my impression that its existence, or at least its importance, is not adequately appreciated. This ligament is reflected from the external oblique fascia over the anterior superior aspect of the pubic spine in intimate contact with the periosteum and is continuous with Poupart's ligament laterally. Its free border superiorly forms a hood which can be lifted sufficiently to receive one suture to approximate it to the internal oblique or conjoined tendon. This firmly closes the vulnerable area immediately above the pubic spine.

Failure to obliterate this defect is responsible for many recurrences, inasmuch as the hernial sac or a diverticulum from a direct hernial bulge is protruded through the defect and provides an effective dilating wedge which enlarges the defect and breaks down an otherwise efficient support.

TECHNIQUE

The usual oblique hernial incision is made over the inguinal canal and is extended inferiorly sufficiently to expose the anterior surface of the pubic spine and superiorly to expose the musculo-aponeurotic juncture of the external oblique muscle. Beginning with the external ring the external oblique aponeurosis is incised over the canal. The edges of the fascia are held apart by retractors to preserve this tissue undamaged for use subsequently as sutures. As the cord is lifted from the canal, the cremasteric fibers and transversalis fascia are dissected from it. The sac in all indirect hernias and the diverticulum in direct hernias (when present) are opened, dissected free down to the neck, and excised. The neck of the sac is ligated as high as possible. This, I believe, is a very important step because failure to do so leaves a cone which acts as a dilating wedge responsible for some recurrences. The transversalis fascia, the lateral border of the internal oblique muscle, and its aponeurosis, and the shelving fold of the external oblique fascia are widely exposed and wiped free of fat. It now becomes necessary thoroughly to expose the superior and anterior surfaces of the pubic spine and the transversalis fascia, and to clean both surfaces of the exposed portion of the external oblique fascia of fat.

As illustrated in Figure 1, a strip approximately 1.5 centimeters wide is cut from the superior mesial flap of the aponeurosis of the external oblique, severing it at the musculo-aponeurotic juncture above but leaving it attached below. It is important to free it down to the inferior border of the pubic spine. Usually it is possible to obtain a strip of 18 centimeters or longer. The free end is fastened to a fascial needle. I use an atraumatic needle of my own design, described elsewhere.

Fig 1 Illustrated are certain essential technical details. The anterior and inferior surfaces of the pubic spine are exposed in order to develop the triangular fascia and to permit freeing of the strip of external oblique aponeurosis to a level below the triangular fascia. The line of incision is indicated by the broken line. The free end of the suture has been fastened to the author's needle which is described in an article now in press (2). The stump of the hernial sac and the tissues in the floor of the canal were blacked out in the drawing to emphasize the borders of the inguinal triangle.

and shown in Figures 1 and 2. Since this needle does not require doubling of the fascia in threading, it obviates the difficulty and the tearing and trauma from dragging a bulky mass of fascia through tissues. The end of the fascial strip is inserted between the flanges in the head of the needle where it is secured with a suture of fine silk passed through drill holes. The needle threaded with fascia is first passed through the triangular ligament from below and anteriorly, and then into the internal oblique (conjoined) tendon lying immediately posterior and mesial to the triangular ligament. It is next passed through Poupart's ligament at its juncture with the triangular ligament and then continued as a continuous suture approximating Poupart's ligament to the transversalis fascia and to the internal oblique muscle and its tendon.

By inclusion of the transversalis fascia in each stitch the floor of the inguinal triangle is narrowed and strengthened and the internal ring with the cord is displaced upward more effectively. The end of the fascial strip is then anchored to the

Fig 2 The fascial suture first seals the superpubic area by passing over the pubic spine and then through the triangular fascia and unites it to the internal oblique aponeurosis. The suture is then continued upward approximating the internal oblique and the transversalis fascia to Poupart's ligament. Each stitch includes the transversalis fascia. As shown in the insert interrupted silk sutures are placed in the gaps between the fascial loops and are used to unite the adjacent edges of the loops. Completed this forms a continuous band of fascia from the pubic spine to the internal ring.

surface of the internal oblique fascia with two encircling and transfixing sutures of silk. Between the fascial loops are placed interrupted sutures of silk to relieve tension and to insure intimate approximation of the layers. The fascial loops are then unfolded and the adjacent edges brought together with interrupted silk sutures to close the gaps and form a solid band of fascia. Silk is used in preference to catgut because it incites less tissue reaction and probably gives stitch service for a longer period of time.

With one or two sutures of silk or chronic catgut Poupart's ligament and the internal oblique muscle are approximated above the cord. These sutures are so placed that the new formed ring fits snugly around the cord.

The edges of the external oblique fascia are then approximated under the cord with interrupted silk sutures. This is usually possible despite the loss of the strip used for a suture. If however this cannot be done without tension a second narrower strip is cut from one of the flaps and used as a pedicled suture to lace the edges of

the flaps, or the superior one is brought down as far as possible and sutured to the internal oblique fascia. Above the cord the edges can always be approximated. The superficial fascia is reunited over the cord and the skin is closed with interrupted sutures.

This technique is applicable in all but a few cases. Occasionally, the aponeurosis of the external oblique is inadequate or unsuitable for use as sutures. This difficulty may be encountered in recurrent hernias. Under such circumstances strips of fascia lata can be substituted. Again, there are those direct hernias in which the internal oblique aponeurosis is either wanting or inserts into the rectus sheath at some distance above the pubic spine. In these cases the inguinal triangle is very broad and there is need of more fascia for support than can be supplied by strips of the external oblique aponeurosis. Since hernias of this type are often asymptomatic, are unlikely to strangulate, usually occur in older, less active individuals, and recur in such a high percentage of instances following operative repair, Andrews has questioned the advisability of treating them surgically. Certainly, if repair is undertaken, such autoplasmic operations as those of Gallie, Halsted, Bloodgood, Andrews, and Wangenstein are indicated. Recently, I have used an operation which will be described in a subsequent publication.

In children, recurrences after the classical operations are rare and autoplasmic operations of any type are unnecessary. This has been emphasized by Hoguet in his statement that in 827 consecutive and personally executed operations for inguinal hernias in children not a single recurrence had developed up to the time of his report.

The use of strips of the external oblique aponeurosis for fascial sutures has certain advantages. The entire operation can be carried out within a single wound not significantly larger than that necessary for any other type of repair. Consequently, the chances of a break in asepsis with infection is minimized. At the distal end the normal attachment of the fascial strip is preserved, thereby a secure anchorage and some blood supply is maintained. For this reason there is less chance of the suture slipping and some questionable vascular aid to survival of the fascia. Finally, the fashioning and placing of the suture requires very little time and inflicts little or no additional trauma to the patient.

The operation strongly fortifies the entire inguinal triangle. This is an important detail in all hernias including even the simple indirect types which, when they recur, recur not infre-

quently in the form of direct hernias. Thus, indirect hernias should be considered potential direct hernias and the repair planned accordingly.

THE RATIONALE OF THE ROUTINE USE OF LIVING SUTURES OF FASCIA

In published and unpublished reports dealing with the operative repair of hernias two facts stand out: (1) most analyses of large series of cases, which have had adequate tests of time, reveal recurrences in excess of 10 per cent in direct hernias and 7 per cent in indirect hernias, and (2) from impressions and from such follow-up observations as are available there has evolved the opinion among several surgeons that living sutures of fascia contribute much to the security of repair and should be used for recurrent and other hernias uncertain or impossible to retain by other means. If fascial sutures give added security and are indicated for repair of these more difficult types of hernias, it logically follows that the more routinely used for the repair of simpler hernias the fewer will be the recurrences. Concurring in this opinion, as expressed by Gallie, I have used routinely the autoplasmic operation here described for all inguinal hernias in adults with the exception of the grossly deficient type of direct hernia discussed previously. Inasmuch as the use of sutures of external oblique fascia does not appreciably increase the duration or trauma of operation or the likelihood of infection, there appears to be no particular contraindication to their use routinely. But why should an operation of this type be used routinely for simple indirect hernias?

Unquestionably, many indirect hernias are cured when the sac is disposed of and the usual subsequent repair is superfluous. Again, most of them and some of the direct hernias are retained adequately by the support of the Ferguson or Bassini types of repair. However, the mere fact that statistics show that recurrences do develop in an astonishingly large number of indirect as well as direct hernias and occur in the hands of the most competent surgeons and in the presence of circumstances which are considered favorable to cure, indicates the need of technical improvement in the operations themselves or their applications. As stated previously, indirect hernias recur not infrequently as direct hernias so that an adequate repair should preclude this possibility as well as cure the primary indirect hernias.

Some recurrence records from representative American and European clinics are presented in Table I with the names of the surgeons who made the report.

Fig. 1 Illustrated are certain essential technical details. The anterior and inferior surfaces of the pubic spine are exposed in order to develop the triangular fascia and to permit freeing of the strip of external oblique aponeurosis to a level below the triangular fascia. The line of incision is indicated by the broken line. The free end of the suture has been fastened to the author's needle which is described in an article now in press (2). Burdick, Gillespie and Higinbotham	1937	22	550		17.1		0.8

Many hernias listed above as direct hernias were combined direct and indirect hernias

These statistics present a low percentage of recurrence when fascial sutures were used. However, included in the table are too few reports of the results from the use of fascial sutures to give a proper comparative evaluation of the method. However, with the exception of the Burdick, Gillespie, and Higinbotham series the recurrence rates in general are definitely lower than are those resulting from other methods of repair. This difference is well shown by the direct comparison in Lytle's series and it becomes more significant in view of the statement made by all three authors including Burdick and associates that the cases in which fascial suture were used were principally the more difficult ones.

Fascia has certain qualities which make it a superior suture material. These have been pointed out by Gillie. He has shown that fascia incites no inflammatory reaction, survives for years if not indefinitely unites with the tissues in which it is imbedded, has great tensile strength and does not stretch under pressure as does scar tissue. This is an important difference because the support from the classical type of repair is as strong as the scar which unites the aponeuroses so that the tendency of scar tissue to stretch and give way under pressure is probably a responsible factor in recurrences. It has been my experience, however, to find Poupert's and the conjoined tendons widely separated and presenting surprisingly little scar or evidence of a previous fusion.

SUMMARY

1. An autoplasmic technique for the repair of inguinal hernias is reported. This technique is original only in so far as it combines certain established principles. It has the advantage of the security obtained from the use of living sutures of fascia without increasing perceptibly the duration and trauma of operation. It utilizes the triangular ligament to solidify the repair by closing the vulnerable area immediately above the pubic spine.

2. The logic for adopting the routine use of autoplasmic repair of inguinal hernias in adults is stated.

Fig 1 Two sources of power, two methods of measuring the negative pressure, and one of regulating the vacuum are portrayed. These can be hooked up in several combinations. Water pump, *a*, is connected to water manometer, and this to bottle. The suction is regulated by valve, *F*, detail of which is seen in upper middle part of illustration. Electric pump can be substituted for water pump with the control valve an integral part of it. Instead of the water manometer, the mercury one, *T*, can be connected between the pump (either water or electric) and connecting bottle.¹

The method is simple, needs only a minimum of attention, takes up very little space, and is highly efficient. As an illustration of the dependability of the electric pump on a suprapubic bladder drainage case, it was run for 9 weeks,

¹Since this illustration was made the American Cystoscope Makers have produced a pump in which the regulating valve and an adjustable mercury manometer are incorporated as integral parts.

practically continuously, with no other attention than oiling the motor every other day. The run was terminated when the patient left the hospital, and there was no indication that it could not have been continued for an indefinite period. In intestinal suction drainage cases it has been run for 3 to 5 days and stopped only because there was no further need for it.

MODIFIED WANGENSTEEN SUCTION DRAINAGE

H DAWSON FURNESS M D F A C S , New York, New York

THE Wangenstein method of suction drainage has proved itself of great value in intestinal obstruction of the non-strangulated type. The method, here described, is I believe a simplification of the original being the same in all particulars except the production of suction.

Suction can be obtained by either a water aspirator or by an electrically driven pump. My experience has been with the motor driven pump designed by Dr. Stedman for suprapubic bladder drainage. The motor (eddy current) operates on 110 volts and 60 cycles. It is small, almost noiseless, can be run indefinitely with no other attention than being oiled every 2 days, does not over heat, and is not harmed by being stalled. It is efficient up to 15 inches mercury negative pressure. In connection with the pump, the makers have designed for me a valve to regulate the vacuum. A manometer of the water or mercury type is used to determine the vacuum.

The details of the valve are shown in the upper middle part of the illustration. At the mid-portion of a tube is an annular perforated flange, x' , on which seats a movable disc valve, x . Attached to either side of this valve are springs, the stronger, m being on the pump side, and the weaker m' on the intake side. At o there is a perforated plug threaded into the tube. Screwing this plug inward compresses the spring m' thus lessening the forces exerted by the stronger spring, m . Decreasing the tension upon it has the reverse effect. It can be so adjusted that the disc will be unseated by negative pressure greater than zero and less than 10 inches (mercury).

For the low pressures used in the Wangenstein method the ordinary gauge is not sufficiently delicate or accurate and therefore a water manometer was constructed along the lines devised by Dr. Donald Gordon. It consists of a tube, 1 inch in diameter with a small opening just above the lower end and a T outlet at the top, one branch of which is connected to the source of suction and the other to the shorter tube of a two tube stoppered collecting bottle. The lower end of the manometer is placed in a glass of water and the position of the small opening so adjusted that the desired vacuum can be obtained. When suction is applied and the stomach end of the tube is obstructed a vacuum is

produced in the bottle and in the manometer thus drawing the column of fluid up into the tube. When the water level in the glass reaches that of the small opening air is drawn into the tube and thus the production of a vacuum greater than that measured by the height of the water column is prevented. With the small opening near the bottom and the large caliber of the tube, the air enters in bubbles and does not blow the water out of the tube as would happen with a small caliber tube. Without a regulatory apparatus on the pump this action is too turbulent.

The valve, which is on the electric motor or on the frame work of the water instrument, is so adjusted that it allows air leakage into the system in just the amount to obtain the desired vacuum.

In practice, it is well to adjust the instrument so that when the desired vacuum is obtained, the water level in the tumbler is just above the small opening in the tube. Should, by chance anything happen to the valve that would impair its action and the vacuum be raised, air would be sucked through the small hole and the manometer act as a safety protection.

A U shaped mercury manometer can be substituted for the water instrument by connecting it with a T tube, one arm to the pump (either water or motor) and the other to the collecting bottle. The only advantage it has over the water instrument is its compactness, a disadvantage is that it is not so accurately adjustable, as 1 inch of mercury is the equivalent of 13.6 inches of water.

Gastric and duodenal suction drainage is best carried on at a negative pressure of 24 to 30 inches of water at the intestinal end of the tube. The pump vacuum should be so adjusted that it, combined with the negative pressure produced by the column of fluid between the stomach and bottle, equals the desired operating value. For example, if one is to work with a suction of 24 inches and the bottle end of the tube is 12 inches lower than the intestinal end, the apparatus should be so adjusted that the manometer will read 12 inches.

When the water aspirator is used, the faucet is so adjusted that the desired vacuum is obtained with the least water flow. The valve at f and the manometer will keep the instrument at the proper level.

can also be prevented by proper pre-operative care, namely absolute abstinence from water or food by mouth. Parenteral administration of fluids must be insisted upon. In practically every case, even if gangrene is present, the acute symptoms will abate in 24 or 48 hours under this regimen.

A much better and more logical operation in reference to anatomical lines can be performed if the symptoms are allowed to subside. An incomplete operation or one performed in two stages should be avoided because those who have had the stage operations have a more serious convalescence than those who have been operated upon in one stage after subsidence of symptoms.

The morbidity and mortality will be greatly increased if the dictum shall prevail that all acute inflammations of the gall bladder should be operated upon at once. More accidents pursuant to the operation will result when they are performed in the acute stage and the mortality will be correspondingly higher.

MOSES BEHREND

THE USE OF DRUGS IN SURGERY

IN early periods of development of surgical therapy standardized procedures often were advocated for given diseases, without consideration of individual variations. Thus many surgeons performed gastro-enterostomies on all peptic ulcers. Routines were followed in the management of toxic goiters without regard for the degree of toxicity or the individual responses of the patients. Experience and a better knowledge of the fundamentals of diseases and their treatment have taught that best results can be obtained only when each patient is studied individually and treated by the method best suited to his problem. Certain routines, however, are still

followed without taking into account the variations in response, and often without an adequate knowledge of their physiological and pathological effects. This is particularly true of the use of drugs in surgery. Many surgeons have standard pre-operative and postoperative orders for all operations, regardless of the nature of the procedure or individual characteristics of the patient.

Disturbances of intestinal motility such as postoperative nausea, vomiting, distention, gas pains, and ileus constitute a high incidence of surgical morbidity. Patients frequently manifest a greater fear of these complications than of the operation. To combat them a variety of drugs is advocated both for prophylactic and therapeutic use. Claims of high efficiency are made for a number of agents if administered repeatedly before and after operation. Such preparations are often used without a thorough understanding of their action. The difficulty of securing human preparations suitable for accurate study is largely responsible for this confusion.

Many surgeons still hold the opinion that morphine "splints the bowel" although physiologists for years have shown that this drug increases small bowel peristalsis. Recent studies have confirmed this action of the opiates, but have shown that they inhibit motility of the right colon, thus explaining their constipating action.

Other drugs, such as eserine, prostigmin, mecholyl and acetylcholine, also have been shown to increase small bowel motility and inhibit colon contractions. Derivatives of the pituitary gland, pituitrin and pitressin have the opposite effect, diminishing small bowel motility but vigorously contracting the colon. Atropine has an inhibiting effect on the entire bowel and when used with morphine will counteract the stimulating action of the latter drug on the small intestine.

EDITOR APPOINTED

THE Board of Directors of the Surgical Publishing Company of Chicago have pleasure in announcing the appointment of Dr. Loyal Davis as editor of SURGERY, GYNECOLOGY AND OBSTETRICS, to fill the post made vacant by the untimely death of Dr. Allen B. Kanavel. Dr. Davis, who is professor of surgery and chairman of that department at Northwestern University Medical School, was appointed assistant editor of this journal in 1927 and associate editor in 1933. Under his able supervision the directors expect that the journal's high standard of excellence achieved in past years will be maintained.

ACUTE INFLAMMATION OF THE GALL BLADDER. A PLEA FOR CONSERVATIVE OPERATION

DOUBTS that have lately arisen as to whether "immediate," early or "delayed" operations give the best results in the treatment of acute inflammatory

conditions of the gall bladder seem to have created a controversy not unlike the discussion that arose years ago concerning the superiority of cholecystectomy over cholecystostomy. Some misunderstanding has arisen as a result of the manner in which the designation of the time of operation has been made. "Emergency" should signify an immediate operation performed within an hour or two after the admission of the patient. The terms "early" and "delayed" are rather indefinite, they may mean any time after the patient has been admitted to the hospital. The term "opportune time," however, seems to me to be the best designation for the proper time to operate on acute cholecystitis or acute empyema of the gall bladder. The opportune time may mean that the operation may be performed immediately upon the admission of the patient or any time thereafter, as the exigency of the case may present itself to the surgeon.

The proponents of the emergency operation fear perforation. Perforation of the gall bladder as a matter of fact is a rare occurrence. In a period extending over 25 years I have had the experience of operating upon one acute perforation of the gall bladder. Pathological anastomoses of the gall bladder with other viscera must be considered perforations but these are not to be confused with the acute types. Perforations of the gall bladder can be prevented if the physician who sees the patient in the first attack of colic would promptly seek the advice of a surgeon. During an attack of acute empyema the patient should be hospitalized immediately and placed under the care of the surgeon. Perforations accompanying acute empyema of the gall bladder

This understanding of the action of drugs enables us to use them more intelligently on our surgical patients. Morphine or other opiates are used to allay pain almost universally before and during the first 24 to 48 hours after surgery. As they increase small bowel peristalsis but inhibit colon contractions, the patient will have bowel contents accumulating in the right colon, where it will remain and liberate gas with resultant distention and gas pains. It seems logical therefore, that these symptoms can be avoided or relieved by evacuating the colon with enemas, augmented if necessary by a pituitary extract. Gas rarely accumulates and distends the small bowel except in cases in which intestinal obstruction or ileus exists. Most gas pains are due to pressure within the colon. Nausea and vomiting following large doses of opiates may be due to a marked small bowel stimulation with reverse peristalsis resulting. When such symptoms occur these drugs should be discontinued or combined

with such agents as atropine or hyoscine to counteract intestinal stimulation. Following surgery on the stomach and small bowel if we suspect atony from trauma and manipulation, we may encourage peristalsis by the use of opiates, prostigmine, or other stimulating drugs.

These likewise might be of value in ileus. We must, however, remember their inhibiting action on the colon. Most postoperative abdominal distention is due to gas in the colon. Here pituitrin or pitressin combined with enemas serve very well to relieve the distress by emptying the large bowel. It is inadvisable to use them repeatedly every few hours except when specially indicated, because of the paralytic effect on the small bowel.

With an understanding of the action of the various drugs employed we can use them more judiciously, and should be able to offer our patients a more comfortable convalescence.

CHARLES B. PUESTOW

.

SIR DAVID WILKIE

1882 1938

MEMOIRS

SIR DAVID WILKIE

THE recent sad death of Sir David Wilkie at the height of his fame and career has been a great loss not only to British surgery but to the whole civilized world for, since medicine differs from most other professions in being international in its scope, he belonged not to Great Britain alone. Wherever there is modern surgery, there will he be mourned.

Born in Kirriemuir, Angus, in 1882, Sir David was educated at the Edinburgh Academy and the Edinburgh University. In 1904 he graduated M.B., Ch.B., and took his higher university degrees of M.D., in 1908 and Ch.M., in 1909. He took the fellowship of the Royal College of Surgeons of Edinburgh in 1907 and that of the Royal College of Surgeons of England in 1918.

After graduation he filled resident posts in Edinburgh, and then studied abroad in Bonn, Berne, and Vienna. In 1914 he was appointed surgeon to the Leith General Hospital, and assistant surgeon to the Royal Infirmary, Edinburgh. During the War he served as surgeon-commander to the Royal Naval Volunteer Reserve. In 1924 he was appointed to the University chair of surgery.

In this period his publications, which were mainly devoted to abdominal surgery, and his powers as a teacher and lecturer were firmly establishing his reputation, not only in his native town of Edinburgh, but throughout the surgical world. In 1929 he was selected by the American College of Surgeons to give the Murphy Oration in Surgery, having been awarded the much prized honorary fellowship of that College in 1926. In the same year he was appointed corresponding member of the French Academy of Surgery and given the fellowship of the Royal Society of Edinburgh. In 1936 he was rewarded with a knighthood and in the same year was made president of the Association of Surgeons of Great Britain and Ireland.

So bare a statement of his record and progress gives, however, no real description of the man. All who knew him admired and respected him. It is, alas, only too often that those who have attained success and fame in their profession are subjected to scathing and spiteful criticism but, although some must have envied him his many gifts, I have never heard, in the many years I have known Wilkie, any unfair censure of his work, or any word other than praise of his character and ability.

His skill and popularity as a teacher are naturally best known to his own students in Edinburgh, but it is characteristic of him that he had the wider outlook, and since his appointment as professor of surgery continued untiringly

to create a department of surgical research, a department which grew in size and reputation until it was known throughout the world and until no surgeon visiting Britain felt that his trip was complete until he had visited Sir David Wilkie. He made Edinburgh a surgical mecca to surgeons in America, England, and the British colonies, while many from other countries have benefited from his skill as a teacher, and what is of much greater value, from his personal magnetism, encouragement and guidance.

In his surgical work his most striking characteristic was the clearness and lucidity of his thought. I have attended very many surgical meetings with Wilkie and have heard him speak. He usually made his remarks late in the meeting, and one was always struck with his ability to pick out the really salient points, to direct attention to the matters of doubt, and to sum up the situation in a few masterly words. Whatever he said and upon whatever subject he addressed the meeting one felt that when he had finished the last word had been said and always his remarks were followed by a round of applause which came spontaneously from surgeons from all parts of the world. It was real and well earned admiration and not the loyalty of local admirers. Whenever he spoke it was manifest that we had the privilege of listening to a real leader of the profession. So greatly was his surgical ability recognized that more and more demands were made upon his time, but his services were always willingly and ungrudgingly given.

He served on the Army Medical Advisory Board, on the Scientific Advisory Committee of the British Empire Cancer Campaign, on the Scottish Board of Health, and on the Medical Research Council. He was also chairman of the Committee of the Ministry of Mines.

Apart from his powers of teaching and of debate he gained fame as a surgeon by his many contributions to surgical literature, each one of which was a master piece of lucidity and contained some new point in the advancement of his craft. The value of his original work was recognized in 1918 when he was awarded the Liston Victoria Jubilee Prize of the Royal College of Surgeons of Edinburgh.

These outstanding abilities of surgery, however, illustrate only one side of his character. His wide activities in the social structure of his native town, in which he was so ably encouraged and assisted by Lady Wilkie, made him beloved by all in Edinburgh. For many years he was chairman of the University Settlement which supervised housing schemes and courses of instruction in general educational subjects and in vocational training. In 1933 he purchased an old cinema, reconstructed it and presented it anonymously to the Settlement as an educational and vocational institute for working class people. There must be many in Edinburgh who feel that they owe him what progress they have made in life. His addresses on many general subjects were much appreciated by large audiences.

It was always a matter of astonishment to his friends that one who had suffered in health should be able to accomplish so much in so many branches of life, and never show any signs of weariness. Any one of the above gifts would have brought a man respect, honor, and admiration, but to those who knew him there was an even greater characteristic, and that was his personal courage. A short time ago all were distressed to hear of his serious illness; from this he recovered and in a short time was back at full work. There was never any suggestion of limiting his activities. He still traveled over long distances to his various meetings and was always cheerful and active. When a short time ago he found he was suffering from a serious disease he faced it with great fortitude and up to the time of his operation discussed general problems impersonally and enthusiastically. Nearly twenty-five centuries ago Euripides said "Take the chance of dying nobly while yet you may lest in a short time death indeed come to thee but a noble death no more." Those who knew of Wilkie's end realize that here was a man who set a fine example of how to die nobly. A great and noble character has left us but there are very many in whose hearts he will live forever.

JAMES WALTON.

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

THE Editor wishes to correct the last paragraph of the review of Dr Cushman's *Memoranda* which appeared in the December 1933 issue page 834 to read

Written in a charming style the material and statistics arranged in an interesting manner by Dr Eisenhardt the reader does not need to be a neurological surgeon to follow the story with profit to his surgical soul.

THE textbook entitled *Massage and Remedial Exercises* can be recommended as a textbook on massage and exercises for physical therapy technicians. Under each subject the author gives a digest of the pathology and symptoms and the medical or surgical treatment. The physical treatment by massage movements and exercise is considered in detail. The illustrations are excellent. The print is small so the volume contains a mass of information. The book should be useful to the general practitioner too as it gives information on the use of massage and exercise. J. S. COLLYER

THE morphology of arteriosclerosis with emphasis upon the vascularity of the vessel wall and its relation to the disease manifestations of the intima is presented by Winternitz Thomas and LeCompte in their recent book. By various processes of clearing the walls and injection of the blood channel the vessel walls as well as changes in the walls themselves become apparent. As expressed by the authors this material is presented with the hope that the prevalent conception of arteriosclerosis as a degenerative process will be replaced by an understanding of the vessel wall as similar to any other organ of the body in that it may be the seat of acute eruptions hemorrhage or proliferative reactions which may undergo a whole series of morbid alterations. The observation that the most vascular areas of the vessel wall are those adjacent to the origin of branches that intramural hemorrhage occurs most frequently in the arteries and also that these same areas are the most frequent site of arteriosclerotic processes stimulated the desire to investigate a possible causal relationship. Studies were made of the embryological development of blood vessels in order to determine the source of the new vessels which occur in disease processes. The vascularity of ves-

sel in health and disease as well as the differences in various age groups was demonstrated and contrasted with that in several species of animals. The pathological changes in the heart valves in endocarditis were found to be strikingly similar to the arteriosclerotic process in the vessels and the question was raised as to a common etiology. The anastomotic connections between the various vasa vasorum and the ability of the vasa to increase in size make possible the maintenance of blood flow through the mural channels when the lumen of the blood vessel is occluded or narrowed.

It is obvious that an immense amount of careful work preceded the publication of this book. It is concise and well expressed. Each point brought out is illustrated from various angles. Most of the illustrations which consist of drawings as well as photomicrographs are in color and are truly remarkable. The concept of the blood as an organ richly supplied throughout with blood vessels of its own opens a new vista in the study of vascular disease.

Not only is the concept of vascular disease greatly advanced by this splendid piece of work but the authors and publishers are to be commended for the beautiful presentation of the material.

M. HERBERT BARKER

IN this country McPheeters is a pioneer in the injection treatment of varicose veins and his monograph on the subject has proved a practical guide for those who are interested in this type of therapy. Almost a decade has elapsed since his book first appeared during which time a vast amount of work has been done in response to the stimulus offered by the injection treatment. The most significant developments have been the search for better sclerosing agents and increased emphasis upon the hydrodynamic problems involved in varicose veins. The latter has resulted in insistence upon high saphenous ligation as a preliminary to injection in selected types of cases. McPheeters has kept abreast of these changes in his new monograph. Like most of the other workers in this country he has adopted solutions of salts of the fatty acids as the preferred sclerosing media. A chapter on preliminary ligation of the saphenous vein has been included. In addition there is a discussion of the causes of failure following injection the principal ones according to the author being inaccurate diagnosis, incorrect technique and failure to ligate when ligation is indicated. The chapter on the treatment of varicose ulcers has been rewritten with amplification of the author's

THE BIOLOGY OF ARTERIO-SCLEROSIS. By M. C. WILSON, M.D. R. M. THOMAS, M.D. and F. M. LE COMPTÉ, M.D. Springfield, Ill. 1931. Baltimore Md. Charles C. Thomas. 95¢

INJECTION TREATMENT OF VARICOSE VEINS AND HEMORRHOIDS. By H. O. McPheeters, M.D. F.A.C.S. A. J. Jamieson, M.D. F.A.C.S. Philadelphia. F. A. Davis Co. 1934.

method of sponge compression. Included in the present volume is a brief, straightforward discussion of the injection treatment of hemorrhoids by James K. Anderson. The injection treatment of varicose veins is here to stay, and McPheeters' monograph will continue to serve as a practical guide to those interested in the method. LEO M. ZIMMERMAN

THE volume of 300 pages by Albert Edward Schlanser¹ is a short, concise manual on diseases of the ear, nose, and throat intended for use in the regular army and is based on many years of experience and observation in peace time. The work is essentially clinical and consequently detailed symptomatology, anatomy, and physiology are purposely omitted.

The book is composed of six chapters dealing chiefly with the patient's complaints followed by a short dissertation on diagnosis and treatment. There are 81 illustrations.

Obviously, it is impossible to condense into 300 pages all the work in otolaryngology but it will enable one to handle confidently and expeditiously each of the many complaints occurring in routine army practice. The student and civil practitioner would find it of doubtful value. JOHN F. DELPH

THE seventeenth volume of a series of research publications of the Association for Research in Nervous and Mental Disease² is made up of the proceedings of the meeting of the Association held in New York on December 28 and 29, 1936.

Like the preceding volumes of this series, this book presents an imposing list of contributors, all of them men in the first rank of American anatomists and neurologists. Five chapters on the anatomy of the pituitary gland, 22 chapters on its physiology, and 15 chapters on general considerations of clinical importance, indicate the comprehensive scope of this work, and it embodies a complete summary of the significant recent advances in our understanding of the hypophysis and its relation to the rest of the organism.

The introductory chapter, by Frederick Tilney, on the various glandular components of the brain, is indeed classical in its treatment. Not only does it present the origin and functional meaning of the various "roof" and "floor" glands, but the origin

¹PRACTICAL OTOTOLOGY, RHINOLOGY AND LARYNGOLOGY. By Albert Edward Schlanser, M.D. Philadelphia: Lea & Febiger, 1938.

²THE PITUITARY GLAND, AN INVESTIGATION OF THE MOST RECENT ADVANCES. Vol. 17 of a Series of Research Publications by the Association for Research in Nervous and Mental Disease. Baltimore: The Williams & Wilkins Co., 1938.

and nature of the individual hypophyseal components down through the various phyla are described with a clarity and simplicity difficult in the handling of such a subject. A short chapter by Oscar Riddle on "prolactin" will no doubt serve to dispel certain existing false concepts of this hormone, and he has indicated the apparent potential clinical usefulness of this substance. Wayne J. Atwell, in a discussion of the enigmatic pars tuberalis, is unable to assign any physiological function to this portion of the hypophysis, though morphological studies indicate some presumptive evidence of function. The chapter on pituitary basophilism by Irving Pardee, together with the section on pituitary cytology by A. E. Severinghaus, adds much valuable data concerning this interesting disease entity, in which there has been, since 1932, an ever widening field of anatomical and clinical research. There is a concise but complete discussion of acromegaly by Tracy J. Putnam and Leo M. Davidoff.

The material in this book is well balanced, and almost all of it is of direct practical value. It should do much toward the stabilization and correlation of the constantly increasing maze of information relative to the endocrine system. JOHN MARTIN

THE popularity of *Electrotherapy and Light Therapy*³ by Kovács is demonstrated by the demand for a third edition within 5 years of its original appearance. The new edition has been thoroughly revised and much new material has been included to bring down to date the knowledge concerning this field. In general the illustrations are well selected, but the many illustrations of various machines could well be replaced by further illustrations of technique.

The book presents the physics, the apparatus, the physiological effects, the indications and contraindications for electrotherapy. The chapters on electrophysics, galvanic current, and electrosurgery have been revised. There have been added new chapters on the relation of electrophysiology to electrotherapy, on short wave diathermy, and on artificial fever by electrical means.

The physics of radiant energy, the physiological effects of the various forms of infrared, visible and ultraviolet radiation, and their clinical applications are also presented. The volume is orderly in arrangement, concise, and sound. It can be recommended to physicians as the best textbook on these subjects.

ASEPTIC NECROSIS OF BONE

I Infarction of Bones in Caisson Disease Resulting in Encapsulated and Calcified Areas in Diaphyses and in Arthritis Deformans

S C KAHLSTROM, M D, Bath, New York, and C C BURTON, M D, F A C S, Dayton, Ohio
D B PHEMISTER, M D, F A C S, Chicago, Illinois

CAISSON disease is the result of injury to tissues by nitrogen bubbles liberated when the body, which in compressed air has absorbed an excess of nitrogen, is too rapidly removed from the decompression chamber. This explanation was first offered by Paul Bert in 1871 and it has been substantiated by the studies of Heller, Mager and Schrotter, Boycott, Damant and Haldane, Bornstein (6, 7), and others.

The amount of nitrogen absorbed varies with the duration and height of the pressure and with the different types of tissues. According to Bornstein, nitrogen saturation for a given pressure is not complete for 7 to 10 hours. Boycott, Damant, and Haldane estimated that there is practically complete saturation for man at high pressures in 5 hours. Bohr and Henriques showed that 100 cubic centimeters of shed blood absorbs at body temperature and one atmosphere pres-

sure 12 cubic centimeters of nitrogen and at 4 atmospheres 48 cubic centimeters. As to the different types of tissues, fat has been found to absorb the largest amount of nitrogen. Vernon reported that at body temperature and atmospheric pressure, fats (lard, olive oil, cod liver oil) dissolve more than five times as much nitrogen as an equal volume of water or blood plasma. He attributed the special tendency of the fat or lipid containing tissues, such as subcutaneous tissues, spinal cord and nerves, to suffer injury in caisson disease to this great solubility. Attention was called to the large amount of fat in the marrow of some bones but no mention was made of known lesions of the bones in caisson disease.

It has also been found (Bornstein) that the less active the circulation of a tissue the more slowly it absorbs nitrogen and in turn, the more slowly is the gas removed from it by the circulation when the increased pressure is reduced, consequently the greater the likelihood of gas bubble formation in it. The nitrogen has been found to damage the tissues most extensively by producing embolism but it also damages by the pressure of gas bubbles extravascularly.

of the literature with a report of 4 cases involving the hip joint in one of which the lesion was bilateral. Symptoms were of relatively short duration, ranging from 4 to 18 months. All had worked from 3 to 4 years in compressed air. In all 4 cases the head of the femur roentgenologically showed scattered areas of reduced density, mixed usually with blurred areas of normal to slightly increased density. There was a variable amount of irregularity of the shadow of the articular cortex and slight flattening of the weight bearing surface of the head in each case. The cartilage space was little narrowed and the acetabulum little changed. Slight marginal lipping of the head was present in 3 cases. Christ concluded that nitrogen gas embolism had occurred in the vessels of the head of the femur producing subchondral necrosis of bone. This was followed by spotted absorption of the necrotic bone with irregularity and sinking in of the articular surface. He mentioned gas bubble formation in the bone but considered it unlikely despite the presence of fat in the medullary canal and the sluggish circulation of the bone marrow.

No case has been reported in the literature in which pathological examination has been made of the bone and joint changes except the grossly examined infected bone which was reported by Twynam.

CASE REPORTS

Four cases of caisson disease with extensive changes in the skeleton have been studied clinically and roentgenologically. One case came to autopsy and in another a biopsy was performed on the involved head of the femur. Extensive lesions were revealed in diaphyses and in epiphyses of certain bones with changes in the joints, all of which appeared to be the result of massive aseptic necrosis of bone secondary to interruption of its blood supply by the liberated nitrogen gas.

CASE 1 Necrosis of epiphyses with secondary deforming arthritis and massive necrosis of shafts of long bones in caisson disease of 35 years' standing.

A 61 year old white male has been a member of the Veterans' Administration Facility, Bath, New York, intermittently since 1930. His chief complaint is pain and limitation of motion in the hips and to a less extent in the left shoulder and knees. He has also

Fig 1 Case 1 Deforming arthritis of both hips and loose body, a

had varicose veins of both legs for many years with swelling, pruritus, and repeated attacks of thrombophlebitis.

The complaint referable to the joints dates back to an attack of caisson disease in about 1901 when he worked on the construction of the Cleveland Water Works tunnel. He was incapacitated for 6 or 7 days due to the severe pains experienced in the arms, hips, and legs. He never completely recovered and by 1907 he limped, favoring the left leg. By 1917 he had adopted the use of a cane and by 1930 his hips were so troublesome that he gave up his trade, that of a gunsmith. He has had a chronic cough most of the time for 5 years and during the past 2 months it has been severe and productive. Roentgenograms of the chest taken at intervals since 1933 show no lung change until 1936, when an infiltrative process was revealed extending into the right upper lobe from the right hilum.

Past history reveals no joint disturbance whatsoever before the occurrence of the caisson disease. There is no history of other illnesses of consequence.

Physical examination Patient is an obese elderly man in fair general condition. He walks with a marked limp favoring the left leg and with the aid of a cane. Regional examination is essentially negative aside from the chest, left shoulder, spine, and lower extremities. There is dullness and impaired breath sounds are present over the right upper lobe, especially posteriorly. There is a rather conspicuous atrophy of the muscles about the left shoulder. Elevation of the left arm is limited to about 90 degrees. There is a definite scoliosis of the dorsolumbar region with convexity to the right. There is practically no abduction of either hip and considerable limitation of both rotation and flexion of both hips. Motion in the knees and ankles is practically normal. There are varicosities and scars from old varicose vein operations in both legs. The lower left leg is slightly swollen. Reflexes are present in both upper and lower extremities.

Laboratory findings Laboratory examinations reveal negative blood Wassermann and Kahn tests, blood calcium and phosphorus, normal, normal white count, red blood cells, 4,000,000. Urine shows albumin with occasional hyaline and granular casts.

Roentgenograms were made of the entire skeleton. The hips showed very extensive changes most marked on the left side (Fig 1). There is marked flattening of the femoral heads with a narrowing of

Acute symptoms of caisson disease appearing a few minutes to hours after too rapid exit from the chamber are referable most frequently to the spinal cord, internal ears, brain, subcutaneous tissues and the limbs. The commonest complaints are severe pains especially in the abdomen ("bends") and in the extremities, ringing in the ears with or without impairment of hearing, hemorrhages in the skin and mucous membranes, bluish mottled discoloration and induration of the skin and subcutaneous tissues and in some cases, paralysis in the extremities. Severe cases may cause cerebral or pulmonary embolic symptoms and death may be an early result. Prompt recompression usually ameliorates and sometimes completely relieves the symptoms. Chronic lesions sometimes result from caisson disease, the most important being impairment of hearing, paralysis from spinal cord damage, and disturbances of the bones and joints.

Pains in the extremities in the early stages have often been referred to as in the joints, particularly the hips less often the knees, ankles, and shoulders. In most instances they clear up but in some cases symptoms and signs similar to those of chronic deforming arthritis have continued. Chronic pains in the course of the bones have also been present in some cases.

Bornstein and Plate and independently Bassoe were the first to describe joint lesions in caisson disease. Bornstein and Plate in 1911 reported 3 cases in which symptoms and signs were present resembling chronic arthritis. A shoulder was involved in one case, one hip in another, and both hips in the third case. Roentgenograms of the hips revealed mottled changes in density in the head of the bone with flattening of its articular surface, irregularity and slight narrowing of cartilage space, and marginal lipping. The findings were considered those of arthritis deformans but they thought that the lesion was due to nitrogen bubbles in the bone bordering on the joint and not to nitrogen in the joint. No more detailed definition of the lesion was attempted.

In his report on the late manifestations of compressed air diseases Bassoe described deforming changes in the joints and also changes

in the bones away from the joints. There were 2 cases of involvement of the hip, 1 of 11 and the other of 13 years standing, in which roentgenologically the head showed mottling and flattening and there was narrowing of cartilage space and lipping which led to a diagnosis of arthritis deformans. In another case there was a similar change in the head of the humerus and lipping of the glenoid margins.

Twynam in 1888 reported the case of a man who had severe symptoms of caisson disease with pain and swelling above the right knee and 2 months from the onset abscess formation which was drained. Later on there was another painful swelling about the right trochanter which was drained and sinuses persisted for 2 years, at which time amputation was performed through the lower third of the femur. The entire shaft of the femur was found to be necrotic and there was involucrum one third of an inch thick surrounding it. This appears to have been a case of massive necrosis of the shaft of the femur with secondary infection which resulted in a picture resembling closely that of pyogenic osteomyelitis.

Chronic changes in the cancellous bone away from the joints was noted roentgenologically by Bassoe three times, once in the upper and once in the lower diaphysis of the tibia and once in the lower epiphysis of the fibula. There were mottled areas of absorption and irregular lines of new bone formation. No definite interpretation was made of these bone changes and there were no reproductions of the roentgenograms in the article. Fortunately, the roentgenograms of the tibial lesions have been preserved and with Dr Bassoe's permission they were compared with roentgenograms showing tibial lesions in some of the cases here reported and found to be quite similar.

A number of reports have since been made of the joint changes in caisson disease. Plate in 1918 reported a case and considered the change to be analogous to arthritis deformans. Burkhardt classified caisson lesions of the joints under the category of arthritis deformans but considered the primary lesion most likely in the adjacent bone. Christ in 1934 published a very comprehensive review

protein nitrogen of the blood and died December 5, 1937.

Autopsy At autopsy the following anatomical diagnoses were made: bronchiogenic carcinoma of the right lung with extension into the superior vena cava, chronic nephritis, cardiac hypertrophy and dilatation, arteriosclerosis, most marked in aorta, duodenal ulcer (five small ulcers), cholelithiasis, cicatrices and pigmentation of legs, scoliosis, ancient, infarcts, ancient, massive, in shafts of both femurs and left humerus and minimal in shaft of left tibia, arthritis, chronic, deforming, of hips and left shoulder secondary to necrosis of heads of femurs and humerus, osteocartilaginous loose bodies in left shoulder and right hip.

The entire right upper lung lobe was involved in carcinoma originating in the bronchus. It penetrated and largely blocked the superior vena cava near its termination. No distinct tumor metastases were found. The heart was moderately hypertrophied but the coronary vessels were patent and smooth throughout. The heart valves appeared normal. There were no signs of infarcts, old or recent, in heart muscle, kidneys, spleen, or brain.

Skeletal structures There was marked right lumbar scoliosis with conspicuous articular proliferation. The trunk bones otherwise showed no outward

changes. The right sixth rib was removed and sectioned. No abnormalities were seen. The left scapula and humerus, both innominate bones, both femurs, and the left tibia were removed. When the left shoulder was opened marked villous proliferation of the synovial membrane and thickening of the capsule were noted. It contained seven osteocartilaginous loose bodies ranging from 1 to 2 centimeters in diameter, some of which were flattened and nodular. The articular cartilage of the glenoid was somewhat frayed but there was no marginal lipping or change in the underlying bone. Roentgenograms showed the same changes in the bones as were present at the examination on admission.

Left humerus The head of the humerus was flattened and its articular surface rough with marked proliferation of the surrounding borders. The articular cartilage was markedly thinned and in places entirely wanting. Section of the humerus (Fig 6) showed 2 cystic areas in the head containing necrotic and gelatinous material. The proximal half of the shaft presented an irregular circumscribed area of necrosis of the medullary portion. It measured 17.5 centimeters in length and varied in width from 20 millimeters in the proximal portion to 4 millimeters in the distal portion. It was surrounded

Fig. 2. Case 1. Central necrotic area in shaft of left femur with calcified and ossified zone of demarcation.

the cartilage plates and marginal lipping especially on the right side. There are scattered areas of reduced density in the subarticular portion of the femoral heads and acetabula inter-perred with areas of increased density.

Anteroposterior and lateral roentgenograms of the lower three fourths of the left femur reveal an oblong area of altered density in the medullary region, measuring 2 1/2 centimeters above the condyles and extending upward for a distance of 18 centimeters (Fig. 3). It occupies almost the entire width of the medullary cavity below and tapers off irregularly above. It is surrounded by a narrow irregular zone of increased density most marked along the mesial and posterior sides. The density of the interior is mottled being lightly increased in most of its extent as compared with that of the normally appearing cancellous bone below the lesion. The shadow of the cortex surrounding this area shows slightly longitudinal breaking but the shaft is not increased in thickness.

A roentgenogram of the right femur shows a similar area in the same region (Fig. 3). The area is 19 centimeters long and is 4.5 centimeters broad at

the lower end in the anteroposterior view. There is a narrow dense zone about the periphery in almost its entire extent. Just beyond its upper limit there is a separate island 1 centimeter in diameter with a dense zone about its periphery. There is a dense streak within 3 centimeters above the lower end in the anteroposterior view and another crossing the involved area transversely 10 centimeters above the lower end seen in the lateral view. The cortex surrounding the area is longitudinally streaked in places and appears lightly irregular in outline in the anteroposterior view. There is a dense island in the external condyle of femur. The areas in the femurs are interpreted to represent masses of old aseptic dead bone that have had a calcareous capsule laid down about them.

A roentgenogram of the left shoulder joint and humerus shows extensive changes. Those in humerus tapering downward for a distance of 20 centimeters (Fig. 4). There is a slight flattening of the articular cortex and slight bony overgrowth at the lower margin of the head of the humerus. There is a dense shadow resembling an osteophyte or loose body at the upper margin of the glenoid and another mesial to the surgical neck of the humerus just below the glenoid margin. There is a mottled increased density in the mesial portion of the upper end of the shaft extending to the anatomical neck and into the upper portion of greater tuberosity. There is an oval area 7 centimeters long extending downward in the shaft of the humerus with a zone of increased density about its periphery most marked at the upper and lower ends. The interior of this area is somewhat mottled in appearance and there is a faint network of increased density extending down the medullary canal from this.

A roentgenogram of the left tibia shows regular lines of sharply increased density extending slightly obliquely across the shaft in the medullary region 12 centimeters below the knee joint (Fig. 5). There is also an island of slightly increased density in the mesial portion of the upper end of the shaft about 1.5 centimeters in diameter though hazy in outline. There is a narrow transverse line partly traversing the medullary region about 7 centimeters above the lower end of the shaft of the tibia which has the appearance of an old growth arrest line. Roentgenograms of the lower thoracic and lumbar spine reveal the end stage change of moderate adolescent scoliosis without any evidence of lesions in the bones of the type seen in the humerus, femurs and tibia.

Roentgenograms of the chest including the cervical spine reveal no changes in the ribs, clavicles and none in the spine and ribs except those resultant from scoliosis. There is a large area of increased density in the region of the right upper lobe which is sharply outlined.

The lung condition was diagnosed as bronchiogenic carcinoma. The patient's chest symptoms fluctuated during the next few months but the cough continued. He gradually lost strength and developed edema of the dependent portions with increased non-

Fig 8 Case 1 Coronal section of posterior portion of external condyle of right femur, showing calcified necrotic area

from the synovial lining. The head was flattened and conical in shape although less pronounced than on the left side. There was an osteocartilaginous body attached by a thin pedicle to the inferior portion of the capsule. Articular cartilages were destroyed on the superior surface of head and opposing surface of the acetabulum and there were marginal osteophytes on both head and acetabulum.

Coronal sections were made of the right femur (Fig 7) and iliac bone extending through the acetabulum. Section of the acetabulum showed sclerosis of the bone bordering on the articulation to a depth of 1 to 2 centimeters and two cavities $\frac{1}{2}$ and $\frac{3}{4}$ centimeter in diameter in the weight-bearing region. One was filled with fibrous tissue and one with fluid (Fig 12). There were also marginal osteophytes. The bone away from the acetabulum was normal in appearance. Section of the femur showed loss of articular cartilage on the weight-bearing portion of the head, with only a thin layer along the inferior portion. The underlying cancellous bone was sclerotic and contained several small cavities, some filled with fibrous tissue and some with fluid. A yellowish dark area at the base of the upper part of the neck of the femur appeared to be calcified infarct. The cortex and medullary portions of the shaft from there down to the middle had a normal appearance. In the lower half of the shaft there was a necrotic area with a dense surrounding zone of demarcation of approximately the same size and location as that seen in the left femur. The roentgenogram revealed a dense mottled area in the posterior part of the external condyle of the right femur. A section through this region (Fig 8) revealed a yellowish, hard, amorphous blotchy area averaging $1\frac{1}{2}$

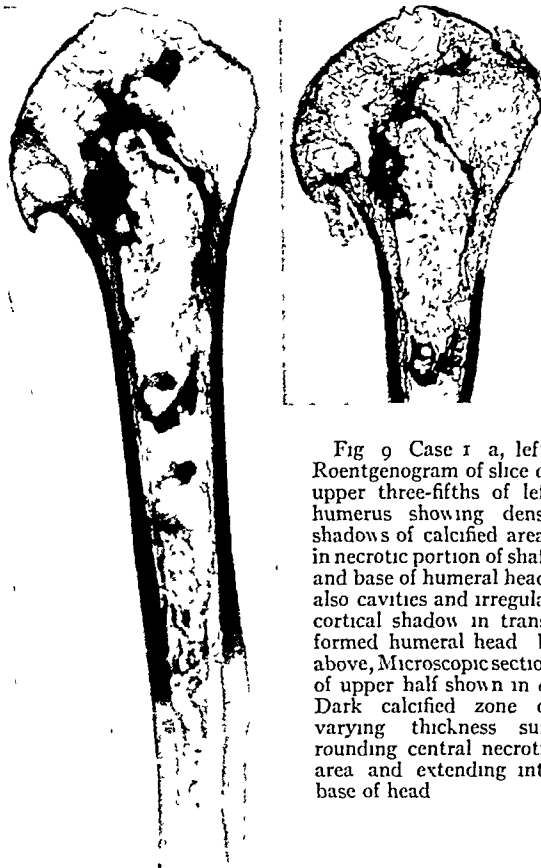

Fig 9 Case 1 a, left, Roentgenogram of slice of upper three-fifths of left humerus showing dense shadows of calcified areas in necrotic portion of shaft and base of humeral head, also cavities and irregular cortical shadow in transformed humeral head b, above, Microscopic section of upper half shown in a. Dark calcified zone of varying thickness surrounding central necrotic area and extending into base of head

centimeters in diameter which also looked like a necrotic calcified region. The epiphysis otherwise and the knee joint were normal in appearance.

The left tibia was normal in external appearance. On section a mottled, grayish yellow, blotchy streak was found in the medullary cavity of the shaft 10 centimeters below the upper end of the bone. There was also an irregular area of slight sclerosis in the cancellous bone of the lateral portion 2 centimeters below the epiphyseal line.

Slices $\frac{1}{2}$ to 1 centimeter thick were cut from the upper three-fifths of the left humerus, the left glenoid, the upper two-fifths of the left tibia, the entire length of the femurs and the acetabula and iliac bones. Roentgenograms of the slices brought out sharply the dense zones of demarcation about the necrotic areas and the blotchy areas of increased density irregularly distributed within them, also the subarticular sclerosis and cavities in the femoral and humeral heads. Large microscopic sections were prepared of the slices of bone, also sections were made of the villous linings of the shoulder and hip joints and of one of the loose bodies which were present in the shoulder.

Fig 6 Case 1 Central necrotic area in upper half of diaphysis of left humerus Deforming arthritis in humeral head and 7 osteocartilaginous loose bodies in shoulder joint

by a dense wall which varied greatly in thickness at different levels being thickest at the upper and lower limits The center contained brownish to grayish friable debris and there were calcareous bridges crossing its middle portion The cortex of the upper half of the shaft was approximately normal in appearance but there was an irregular zone of cancellous bone of increased density between it and the wall of the central necrotic area The lower half of the humerus and the elbow joint were normal

The capsule of the left hip was somewhat thickened and the synovia showed moderate villous arthritis with lymphocytic infiltration The femoral head was markedly flattened devoid of articular cartilage and surrounded by marginal osteophytes There was destruction of articular cartilage of the glenoid which was changed in shape to fit the altered head and there was a long osteophyte extending outward from the superior margin of the acetabulum There was also a marginal osteophyte in the region of the cotyloid notch An osteocartilaginous body was attached by a pedicle to the inferior portion of the cap ule

Fig 7 Case 1 Section of femurs showing remnants of infarcts in lower half and resolved but deformed femoral heads Partly calcified incompletely resolved area of necrosis at a

Coronal sections were made of the left femur (Fig 7) and left innominate bone passing through the hip joint The acetabular portion of the innominate bone showed marked sclerosis with a few scattered cystic areas in its mesial portion The bone away from the acetabular region was normal in appearance

The shaft of the left femur was normal to external appearance The cut surface of the flattened head showed it to consist of irregular dense bone surrounding cystic areas beneath the articular surface and extending into the proximal portion of the neck Osteophytes was most marked at the lower margin The remaining portion of the neck and upper half of shaft of the femur appeared normal The distal half of the shaft contained an encapsulated area of necrotic grayish friable debris measuring 15 centimeters in length and varying in width approximately from 4 millimeters at its upper end to 25 millimeters at its lower end which extended to within 2 centimeters of the epiphysis It was surrounded by a dark hard zone varying from $\frac{1}{4}$ to $\frac{1}{2}$ centimeter in thickness There were areas of cancellous bone and calcareous deposit within the necrotic debris The cortex surrounding the necrotic area was approximately normal in appearance but there was sclerosed cancellous bone about the dense capsule The lower epiphysis articular surface of the femur and the lining of the knee were normal in appearance

The right hip The capsule of the right hip was also thickened and there were many villi springing

Fig 12 Case 1 Microscopic section of the upper portion of the right femur and of the acetabulum showing deforming arthritis

cartilage. These changes gave rise secondarily to villous synovitis and osteocartilaginous loose bodies. A section of one of the loose bodies showed it to consist of a center of calcified fibrocartilage and an outer portion of irregularly laminated fibrocartilage and calcified cartilage.

Figure 11 is a roentgenogram of coronal slices of the right femur and acetabulum and Figure 12 a microscopic section of the upper portion of the femur and acetabulum.

The changes in the head of the femur and acetabulum were similar to those in the head of the humerus. Microscopically, the articular surfaces on both sides of the joint were covered by an irregular layer of fibrocartilage. In places it was incomplete and bare sclerosed bone with fibrous marrow bordered on the joint. There were subchondral cavities filled with fibrous tissue or with coagulum and there was marked osteophyte formation at the limits of the articular surfaces. The synovia showed a villous arthritis and there was a small island of bone imbedded in capsule at the inferior portion of the joint. At the base of the neck both mesially and laterally

Fig 13 Case 1 Microscopic section of lower half of shaft of right femur showing central necrotic area and calcified zone, \times , about its periphery

there were irregular islands of calcified fibrous marrow indicative of ancient bone necrosis. The head presented the picture of ancient aseptic necrosis with secondary collapse, invasion, and transformation similar to that which has been observed following intracapsular fracture of the neck with necrosis of the head, bony union of the fracture and subsequent weight bearing.

The rest of the upper diaphysis showed no change. Microscopic examination of a section of the lower half of the shaft of the right femur (Fig 13) revealed a central area of necrosis of cancellous bone and marrow with a small amount of granular calcification similar to that seen in the upper diaphysis of the humerus. The dead trabeculae were unaltered in form as can be seen in Figure 12. There was a surrounding narrow zone of demarcation of calcified and partly ossified connective tissue. In places the connective tissue had grown for short distances into the necrotic zone, and in the upper limits were broad bands and islands of calcified tissue. There was a surrounding zone of living trabeculated bone and marrow, except at the upper end where the calcified

Fig 10 Case 1 Section of wall about necrotic area in Figure 9 b showing 1 necrotic bone and marrow with calcareous islands 2 fibrosed calcified and partly ossified wall 3 surrounding living cancellous bone and marrow

Figure 9 shows the appearance of the roentgenogram of the slice cut from the humerus and of a microscopic section of the upper half of the slice. Under the microscope the central region of the shaft was found to consist of necrotic cancellous bone and marrow with blotchy areas of calcification. About the upper and lower limits of the necrotic area there was a broad layer of heavily calcified connective tissue and debris. Along the sides the zone of demarcation was much narrower. The lateral wall consisted of a narrow zone of calcified tissue in its upper three fourths and of uncalcified dense fibrous tissue in its lower fourth. There was also an uncalcified fibrous wall along the lower two thirds of the mesial wall. Surrounding this zone were living cancellous bone and fatty marrow. A microscopic section of the calcified lateral wall is shown in Figure 10. The internal portion consisted of small trabeculae with empty lacunae and of necrotic marrow. The outlines of the dead fat cells were remarkably well preserved. They were generally filled with an albuminous substance (*edema ex vacuo*). There were in places large and small calcareous granules. The zone of demarcation consisted of fibrous tissue which was extensively calcified and in places had been transformed into bone. It incorporated some dead trabeculae which had not yet been absorbed and replaced by new bone. Outside of this was living cancellous bone and fatty marrow. The humeral head was flattened and contained three cystic areas—two in its lower part and one in its upper part. They were filled partly with a coagulum and partly with fibrous tissue. The joint surface of the superior and lateral portion of the head was covered with normal articular cartilage and underlying cortex. The rest of the head was covered with an incomplete thin layer of fibrocartilage and the articular cortex was bare and sclerosed in places. There was an osteophyte at the lower limit of the articular surface and a notch at the junction of the normal and transformed articular surfaces at the top of the head.

Fig 11 Case 1 Roentgenogram of slice of right femur and acetabulum showing arthritis deformans and walled off infarct in lower half of femoral shaft

Numerous villi sprang from the synovia. At the base of the head in its upper portion a partly transformed calcified necrotic zone separated it from the greater tuberosity.

The changes in the head are best explainable on the basis of a massive necrosis of all except its superior and lateral portion with death of overlying articular cartilage. The subsequent changes have consisted in gradual invasion, absorption and replacement of the necrotic portion by cancellous bone and cystic cavities and calcified tissue at its base. The dead articular cartilage has been partly replaced by an incomplete layer of thin fibro-

Fig 16 Case 2 Necrosis of heads of femurs in caisson disease of 4 years' duration with sequestration of superior portions from weight bearing

Fig 17 Case 2 Left shoulder Large portion of head of humerus shows irregular reduction in density with zone of increased density about it

Fig 17

less demarcated from the surrounding head by the zone of reduced density. Its articular surface was dense, smooth, and depressed mesially where it extended to the fovea. The bone of the head and neck surrounding the demarcated area was somewhat mottled and increased in density. The shadow of articular cortex of acetabulum was intact and the cartilage space of the joint was approximately normal in width.

Roentgenograms of the shoulder showed blotchy reduction in density with a surrounding zone of increased density in the head of each humerus, more marked in the left (Fig 17).

The diagnosis was made of caisson disease producing large areas of aseptic necrosis in the heads of the femurs, which, as a result of too much weight bearing, had been separated from the surrounding living bone. A biopsy was performed of the left hip by Dr Walker. The cartilage looked pale. With a gouge some bone was removed from the neck of the femur. Aerobic and anaerobic cultures and guinea pig inoculations for tuberculosis gave negative results. Evidently the lesion of the head was not entered as microscopic sections of the bone removed showed atrophic living bone with an increase of fat and in some places of fibroblasts in the marrow spaces.

The patient remained in the institution with little change in his condition. February 9, 1935, a roentgenogram of the hips showed slight progression of the disease, the separated area of the head of the right femur being slightly more depressed. May 1, 1935, because of continued pain in the right hip an operation was performed at which cartilage and necrotic bone were removed, reducing the head to about one-fourth its normal size. Microscopic sections were made of a piece of the excised head. It contained bony trabeculae, the lacunae of which were entirely devoid of cells. The marrow spaces were partly filled with white fibrous connective tissue much of which was necrotic and in places the bone was being eroded along its surface. The microscopic

picture was that of aseptic necrosis of bone with subsequent invasion and partial absorption by connective tissue. The patient after a few months walked in a caliper splint but the joint continued to be weak and painful and he was unable to work. A roentgenogram of the left hip taken 3 years after the first showed only slight progression of the process.

CASE 3 B W, male, aged 54 years, was admitted to the University of Chicago Clinics, January 3, 1938, because of spastic paralysis in the lower extremities. In 1908 while working at bridge construction he came out of a caisson of 40 pounds' pressure in 5 minutes. Twenty minutes later he suffered severe pains in the abdomen, arms, and legs, and was removed to a hospital. There he developed in addition paralysis of the lower extremities and bladder and was confined for 4 months. The pains gradually disappeared but the limbs remained weak and became spastic.

Since 5 months after the injury the patient had walked with a cane but always with great difficulty. Sexual impotence had been present since the injury. He had had no pains in the limbs until 2 years ago since which time there had been frequently a dull ache, especially at night, over the lower half of the right tibia.

Past history Patient could not recall any case of illness before accident in 1908, no history of venereal infection.

Physical examination revealed a well nourished male, weight 200 pounds, blood pressure, 150/90. Regional examination aside from the lower extremities was essentially normal, except for the right pupil which was slightly larger than the left and both pupils reacted sluggishly to light. He walked slowly with a spastic gait. Both lower extremities were spastic and movements of the joints were carried out with difficulty. The patellar and Achilles reflexes were exaggerated and clonus was easily incited. The hip, knee, and ankle joints showed no palpable changes but motion was restricted in them due to the spasticity. There was hypesthesia and marked dimi-

Fig 14 Case 1 Wall of necrotic area. a Necrotic bone and marrow within b calcified fibrous zone of demarcation c surrounding living cancellous bone and marrow. $\times 25$

wall merged with the compact cortex laterally. Figures 14 and 15 show the microscopic appearance of the zone of demarcation.

The articular cartilage and synovial lining of the knee joint were normal which would indicate that the necrotic lesion did not primarily reach the articular surface of the joint. A microscopic section of the yellowish dense area in the posterior part of the external condyle showed it to consist in its deeper portions of old dead bone with cancellous spaces filled with a partly calcified sparsely cellular connective tissue. In its peripheral portion were living bony trabeculae and the lesion was surrounded by living cancellous bone and fatty marrow. Microscopic examination of the yellowish dense area in the upper third of the shaft of the left tibia showed a picture similar to that in the external condyle of the femur. These were obviously old areas of necrosis with fibrous invasion, calcification and incomplete replacement by new bone. The one in the condyle of the femur appeared to be an infarct which arose separate from that in the diaphysis.

CASE 2. L. O. B. aged 37 years was admitted to the Veterans Administration Dayton Ohio in June 1934 because of pain and stiffness in both hips of 4 years duration. He states that in 1930 while working in a caisson there was leakage of gas from a neighboring plant and the crew was hurriedly taken out without gradual decompression. The patient developed the bends and was placed in a recompressor. On removal the attacks recurred so that he was returned to the recompressor and kept for 1 day. He was sent to a hospital with bleeding from the ears, nose and mouth and delirium which necessitated restraint. Ecchymoses developed in the skin of various parts of the body. He has had pain in the hips and legs from the time of admission to the hospital to the present although in diminishing severity. At some pain and stiffness in the shoulders. In 1931 he went into compressed air again to see if it

Fig 15 Case 1 High power view of zone of demarcation. a Necrotic border b calcified zone c surrounding living bone

would benefit his hips. He thought the pressure affected his heart and the joints were not benefited. The pain and stiffness in the hips have advanced to a point where he has had to discontinue all work.

Past history. He was a steam fitter before being a caisson worker. He has had the usual diseases of childhood and smallpox, influenza and pneumonia, gonorrhea in 1923. He denies having syphilis. No history of joint trouble was elicited before the onset of the caisson disease. He suffers from headaches and attacks of dizziness. He smokes and drinks alcoholics moderately.

Physical examination. The patient is short stocky and somewhat overweight. He walks carefully with a waddling gait. Regional examination is essentially negative aside from the hips and shoulders. There is slight limitation of motion in both shoulders more marked in the left. Motion in the hips is limited in all directions to about one half normal and forced motion is painful. There is normal range of motion in the ankles and knees.

Laboratory findings. Basal metabolic rate was -10 blood Wassermann and Kahn negative. Cytology and chemistry of blood analyses including calcium, phosphorus and uric acid were within normal limits.

Roentgenograms were taken of the hips (Fig. 16). The head of the left femur showed a large spherical area of mottled density in the weight bearing portion including the joint surface and extending to the junction with the neck. It was separated from the surrounding bone by a broad zone of reduced density and its articular surface was depressed 3 to 4 millimeters. The rest of the articular surface of the head and that of the acetabulum appeared even in outline and the cartilage space was of normal width. The medial and inferior portions of the head were slightly increased in density and there was haziness and slight increase in density of the bone surrounding the demarcated spherical area and extending downward into the adjacent portion of neck.

The right femur showed a similar area in the same region of the head which was larger, more dense and

Fig 21

was like that of Case 1 and very different from that seen in bone syphilis. No treatment was advised for the caisson disease but treatment was recommended for the lues.

CASE 4 L. P., male, aged 55 years, entered the University of Chicago Clinics, April 11, 1938, because of long-standing stiffness and pains in the hips, knees, and shoulders. In February, 1917, the patient worked for 8 hours in a caisson with pressure of 20 pounds. He came out in 4 minutes and 30 minutes later developed severe pains in the abdomen, legs, and arms. He had hemoptysis and hematemesis and was very ill for several days. He gradually improved and in 3 months was able to work but still had pains in both upper and lower extremities. Five months after the accident he had to give up work because of stiffness and soreness in the hips. These symptoms have persisted and he has gotten around with increasing difficulty. Pain and stiffness in the shoulder have also continued. Swelling developed in the lower legs and the skin became discolored with the development of leg ulcers. He has been unable to do any kind of work for several years.

Past history disclosed the usual diseases of childhood and gonorrhea at 10 years.

Physical examination revealed a well nourished male who moved about with great difficulty. Regional examination was essentially negative aside from the extremities. There was limitation of elevation of the arms to about 90 degrees and forced motions caused pain in the shoulders, marked

nition in tactile sense below the knees Blood Wassermann 4 plus Kahn 3 plus

Roentgenograms were made of the entire skeleton. Areas of increased density were revealed within the shafts of the lower ends of the femurs the upper ends of the fibulas and the upper and lower ends of the tibias. In the right femur the lower three fifths of the shaft was involved. There was a dense irregular zone of demarcation at the junction of the cancellous and cortical bone of the metaphysis and irregularly along the walls of the medullary cavity above (Fig 18). A similar condition was seen in the upper third of the shaft of the right tibia and in the upper metaphysis of the right fibula (Fig 19). There was a similar dense blotchy area in the lower end of the right tibia 6 centimeters long beginning 1½ centimeters above the epiphyseal line (Fig 20). In the left femur the involvement began just above the lower epiphysis and extended upward throughout three fifths of the shaft (Fig 21). The lesions in the

Fig 19 left Case 3 Demarcated dense zones in upper portions of right tibia and fibula

Fig 20 right Case 3 Right tibia and fibula Lower metaphysis involved in tibia and free in fibula

left tibia and fibula resembled those of the right (Figs 22 and 23). The left humerus showed a pointed area of increased density in the region of the lesser tubercle. There was no change in the head of the humerus or shoulder joint (Fig 24). Roentgenograms of the rest of the skeleton revealed no abnormal changes. It was particularly noteworthy that the heads of the femurs and hip joints were uninvolved.

Diagnosis. The condition was diagnosed as a late stage of caisson disease with spastic paraplegia of the lower extremities and areas of incompletely resolved and calcified aseptic necrosis of the femurs tibias fibulas and left humerus. Lues was diagnosed because of the positive Wassermann and Kahn tests and the sluggishness and inequality of pupil. But the roentgenographic appearance of the bone lesions

Fig 27

The lesions in the shafts are remarkable in that they are much more numerous and extensive than in any case of bland infarction or aseptic necrosis of bone found reported. The necrosis was of the interior of the diaphysis in all instances and because of the long time that had elapsed since the initial lesion it was difficult to know how much if any of the internal portion of cortex was involved. Creeping invasion and substitution of the dead bone by new bone may have reduced materially the size of the necrotic area before the process came to a standstill with calcification of the surrounding fibrous zone. Preservation of circulation to the cortex would tend to guard against the occurrence of pathological fracture but the presence of central necrosis producing weakness of bone would set up a reparative stimulus leading to creep-

tion of the hip, fracture of the neck of the femur followed by bony union (Phemister) and idiopathic necrosis in adults (Chandler)

ing replacement of some of the dead bone by new bone. Once the diaphysis is sufficiently strong to support the part, the stimulus for substitution would come to a standstill and the remaining portion become encapsulated. One reason why these large diaphyseal lesions have not been heretofore recognized may be the slightness or absence of associated symptoms and the failure of occurrence of pathological fractures. On the other hand, the pains in the limbs during both early and later stages are doubtless due in some cases to the bone necrosis.

It is difficult to state whether the lesions in the bones produced by the nitrogen gas were the result of nitrogen embolism or of nitrogen accumulation within the medullary cavity and direct compression of blood vessels and other tissues or a combination of the two. Lesions of the soft parts are known to be produced by both methods. Points in favor of nitrogen embolism are: (1) The lesions were frequent (in three cases) in the heads of femurs where end arteries are known to be frequently found, (2) the metaphyses of the lower end of the femur and of upper end of fibula and both ends of tibia were affected in some cases while their epiphyses escaped,

Fig. 25. Case 4. Left hip deformed with sequestrum at top of flattened transformed femoral head. In right hip are noted osteophytes and mottled density of head.

limitation of motion in all directions in both hips, knee and ankle motion was slightly limited.

Moderate swelling of the lower half of the legs was noted and also brawny induration, pigmentation and small ulceration of the skin were present. Little muscle weakness was found in the legs and forearms. The reflexes were normal throughout. No disturbance of sensation of the skin was noted in any part of the body. Blood pressure was 130/76. Urine and blood examinations were essentially negative. Wassermann and Kahn tests were negative.

Roentgenograms were made of the entire skeleton. Extreme deformity of both hips was noted more marked in the left (Fig. 25). The head of the left femur was flattened and the underlying bone was irregularly increased in density. The depressed dense area at the middle of the top appeared to be a detached piece of necrotic cortex such as is often seen in the collapsed femoral head that is necrotic following traumatic dislocation of the hip fracture of the neck of femur, slipped epiphysis or Legg-Perthes disease. The cartilage space of the joint was narrowed and there was marked osteophyte formation at the acetabular margins. The right hip showed narrowing of the cartilage space of the joint, increased density and mottling of the head of the femur andipping of the lower articular margins of the head and of the upper margin of the acetabulum. There was a half moon shaped shadow of blotchy increased density in the upper portion of the head of the left humerus bordering on the articular surface which was irregular in this region (Fig. 26). The greatest increase in density was at the junction of head and neck and there was a narrow irregular streak of increased density extending downward for approximately 3 centimeters into the shaft. The right humerus showed a similarly situated area of increased density which was more uniform and the articular surface of the area was somewhat irregular and flattened. The process did not extend into the shaft of the humerus.

Somewhat hazily outlined areas of increased density were apparent in the interior of the diaphyses of the lower ends of the femurs, both ends of the tibiae and questionably the proximal end of the humeri as seen in Figures 27, 28 and 29. The appearance differed from that of the corresponding

Fig. 26. Case 4. Mottled increased density in head of each humerus with extension into metaphysis of left.

leg bones in Cases 1 and 3 in that dense lines of demarcation had not yet formed about the periphery of the lesions. The epiphyses of all three bones were free of involvement and no changes appeared in the joint spaces.

A diagnosis was made of caisson disease with necrosis and partial replacement by new bone and partial calcification in the heads of the humeri and femurs and necrosis with less complete reorganization and calcification in the diaphyses of femurs and tibiae.

In view of the similarity of roentgenographic changes in the bones and joints in the 4 cases and of the established nature of the pathology in Cases 1 and 2, the evidence appears to be conclusive that the primary lesion is an accumulation of nitrogen gas in the bones—whether intravascular or extravascular will be discussed later—with interference of circulation and a resultant massive aseptic necrosis. In the head of femur or humerus the necrotic lesions may break down and be invaded and eventually replaced by new bone or fibrous tissue. Invasion of portions of the epiphysis may be followed by calcification and arrested transformation, especially in portions of the epiphysis away from the articular surface. Involvement of articular cortex and cartilage leads to the slow development of arthritis deformans with or without osteocartilaginous loose bodies. These changes are in keeping with those seen in the head of the femur and hip joint years after interruption of blood supply of the head of femur as by slipped epiphysis, certain cases of traumatic disloca-

Involvement of articular cortex and cartilage leads to the slow development of arthritic deformities with or without osteocartilaginous loose bodies. These changes are in keeping with those seen in the head of the femur and hip joint years after interruption of blood supply of the head of femur as by slipped epiphysis, certain cases of traumatic dislo-

and contractures of the hind limbs. Animal was sacrificed in 155 days. The spinal cord was examined by Dr Cloward. It showed marked degeneration in distribution of anterior spinal artery of lumbosacral region. The muscles of the hind limbs were dissected from the skeleton. In places they were pale and shrunken, especially the adductors. Microscopic sections showed extensive-scattered replacement by fat. The bones of the hind limbs were roentgenographed, split open, and the left femoral head was sectioned for microscopic study. No changes were found aside from slight atrophy.

Twelve cubic centimeters per kilogram body weight injected in one dog caused death in 10 minutes from embolism.

Ten cubic centimeters per kilogram body weight injected in another animal caused death overnight from embolism.

Six and seven-tenths cubic centimeters per kilogram body weight injected in one dog caused no symptoms afterward. Animal was sacrificed in 94 days. The bones of the hind limbs were roentgenographed and split and microscopic sections were made of the head of left femur. No pathological changes were found in the bones.

The absence of necrosis in the bones of the 4 dogs whose hind limbs were partly or completely paralyzed by the air embolism may possibly be considered as evidence favoring the view that the bone lesions in caisson disease are due rather to gas liberated in the medullary cavity under sufficient pressure to asphyxiate the tissues than to embolism.

SUMMARY

The literature of skeletal lesions of caisson disease is reviewed.

Four cases of caisson disease of long standing in adult males are reported in which there was evidence that multiple infarction of large to small portions of long bones occurred as a result of damage by liberated nitrogen gas. All cases were studied clinically and roentgenologically, and the diagnosis was confirmed in one case by autopsy and in another by biopsy.

Late changes in the necrotic areas varied with the location and duration of involvement.

When the necrotic bone was situated in the epiphyses and bordered on joints, varying amounts of collapse of the weight-bearing portions, invasion and replacement by new bone, and calcification of non-substituted portions were noted. Articular cartilage overlying involved areas broke down and was

replaced by fibrocartilage and more or less extensive arthritis deformans was established, accompanied in some instances by the formation of osteocartilaginous loose bodies. Support is furnished for the theory that arthritis deformans may be due to vascular blockage and necrosis of bone underlying articular cartilage.

When the necrotic bone was situated in the diaphyses or in epiphyses away from the articular surfaces, collapse did not occur and there was evidence of some invasion and replacement by new bone, as judged by the presence of irregular cancellous living bone surrounding and even penetrating the persistent areas. Complete replacement of some of the smaller areas had probably come about. But in the case of large areas replacement after advancing to the point of restoring approximately normal strength to the bone, came to a standstill as shown by repeated roentgenographic studies at long intervals, and the fibrous wall about them became more or less extensively calcified and ossified. Small necrotic areas were found, as one in the femoral condyle, invaded by connective tissue and extensively calcified. Scattered calcification also took place to some extent in the large central uninvaded encapsulated areas.

The encapsulated and calcified areas of necrosis in the diaphyses produced characteristic pictures in roentgenograms.

Uncertainty prevails as to whether the necrosis was produced by nitrogen gas obstruction of end arteries of the bones by embolism or by direct pressure on blood vessels and other tissues after liberation from solution in the fat of the bone marrow or in some other unexplained way. The facts that the long bones of the extremities, which are rich in fatty marrow, were the only bones involved, that fat absorbs relatively very large amounts of nitrogen and that nitrogen bubbles would be absorbed slowly from the marrow tissues because of the known sluggishness of the intra-osseous circulation, favor the theory of direct pressure of the gas on vessels and other tissues within the bone. But the extensive involvement of the diaphyses in some cases without involvement of epiphyses, and the involvement of the epiphyses, especially of the head of the femur, without involvement of

which would favor embolism of the branches of their nutrient arteries. Points against the embolic theory are: (1) The enormous size and symmetrical distribution of the necrotic areas. With such extensive infarction of the bones produced by embolism, similar infarction of the spleen and kidneys might be expected and this was not found at autopsy in Case 1. Also in the presence of such extensive embolism of bones death might be expected to result from embolism of soft parts supplied by end arteries as brain, lungs, kidneys, intestine, etc. (2) Absence of involvement of the bones of the trunk.

In favor of the local pressure on blood vessels and other tissues of nitrogen gas accumulated in the medullary cavities is the limitation of the process to the extremity bones. The extremity bones are rich in fatty marrow while the trunk bones which have higher temperatures than the extremity bones (Huggins and Blockson) contain hematopoietic marrow. Since fats and lipoids are known to absorb approximately five times as much nitrogen as other tissues more nitrogen should be liberated within the extremity bones than within the trunk bones in caisson disease. Bornstein drew attention to the fact that the sluggishness of circulation in the bone marrow would mean less rapid removal of the gas from the bone marrow than from other tissues and consequently greater likelihood of necrosis from prolonged pressure. Larén has shown that when a hydrostatic pressure of 180 centimeters or more is maintained in the medullary canal of the femur of the dog by means of an infusion flask connected with a cannula passing through the cortex massive diaphyseal necrosis of the medullary tissues and the cortex takes place.

Experience in the treatment of aseptic necrosis of the head of the femur in fractures of the neck with bony union Legg Perthes disease and slipped epiphysis indicates that the best possible management of any form of necrosing lesion of the head of the femur (including caisson disease necrosis) is prolonged abstinence from weight bearing thus permitting reorganization of the necrotic area and if possible replacement by new bone with the avoidance of collapse of the head.

ANIMAL EXPERIMENTS

A search of the literature on experimental caisson disease failed to reveal a report of examination of the skeleton for evidences of lesions produced by liberated nitrogen gas.

Experiments on Dogs

One of us (D B P) in the department of surgery of the University of Chicago attempted to produce bone necrosis on seven dogs by arterial air embolism in the following manner. The dogs were anesthetized with ether and the head lowered in extreme Trendelenburg position. Aseptic technique was used and the right femoral artery was exposed and ligated. An arterial clamp was applied 1 inch above and the artery was opened near the ligature. A ureteral catheter, large enough to fill the artery, was introduced and after removal of the clamp pushed upward until its tip was in the aorta just above the bifurcation. Air varying in amounts from 6.7 to 12 cubic centimeters per kilogram body weight was then slowly injected. The air passing into the arteries produced crepitation in the lower extremities. After the wounds were closed the surviving animals were left in the Trendelenburg position for 3 hours to decrease the amount of air embolism in heart, lungs and brain and to prolong that in the lower extremities.

Protocols of Experiments

Seven cubic centimeters per kilogram body weight injected in one dog caused paralysis of hind legs death in 7 days. The femurs and tibiae were split longitudinally and no gross changes were observed. Microscopic section of upper end of left femur showed no abnormality.

Eight cubic centimeters per kilogram body weight injected in one dog caused partial paralysis of hind legs. Infection developed in the operative wound and killed the dog in 8 days. Bones of both hind limbs were split open. No gross evidence of necrosis was seen anywhere.

Ten cubic centimeters per kilogram body weight injected in one dog produced partial paralysis of hind legs which slowly improved to some extent. Death occurred from distemper in 14 days. The bones of the hind legs were removed, roentgenographed and split open. A microscopic section was made of the upper end of the femur. No gross or microscopic change was found.

Ten cubic centimeter per kilogram body weight injected into one dog produced complete paralysis.

and contractures of the hind limbs. Animal was sacrificed in 155 days. The spinal cord was examined by Dr. Cloward. It showed marked degeneration in distribution of anterior spinal artery of lumbosacral region. The muscles of the hind limbs were dissected from the skeleton. In places they were pale and shrunken, especially the adductors. Microscopic sections showed extensive-scattered replacement by fat. The bones of the hind limbs were roentgenographed, split open, and the left femoral head was sectioned for microscopic study. No changes were found aside from slight atrophy.

Twelve cubic centimeters per kilogram body weight injected in one dog caused death in 10 minutes from embolism.

Ten cubic centimeters per kilogram body weight injected in another animal caused death over night from embolism.

Six and seven-tenths cubic centimeters per kilogram body weight injected in one dog caused no symptoms afterward. Animal was sacrificed in 94 days. The bones of the hind limbs were roentgenographed and split and microscopic sections were made of the head of left femur. No pathological changes were found in the bones.

The absence of necrosis in the bones of the 4 dogs whose hind limbs were partly or completely paralyzed by the air embolism may possibly be considered as evidence favoring the view that the bone lesions in caisson disease are due rather to gas liberated in the medullary cavity under sufficient pressure to asphyxiate the tissues than to embolism.

SUMMARY

The literature of skeletal lesions of caisson disease is reviewed.

Four cases of caisson disease of long standing in adult males are reported in which there was evidence that multiple infarction of large to small portions of long bones occurred as a result of damage by liberated nitrogen gas. All cases were studied clinically and roentgenologically, and the diagnosis was confirmed in one case by autopsy and in another by biopsy.

Late changes in the necrotic areas varied with the location and duration of involvement.

When the necrotic bone was situated in the epiphyses and bordered on joints, varying amounts of collapse of the weight-bearing portions, invasion and replacement by new bone, and calcification of non-substituted portions were noted. Articular cartilage overlying involved areas broke down and was

replaced by fibrocartilage and more or less extensive arthritis deformans was established, accompanied in some instances by the formation of osteocartilaginous loose bodies. Support is furnished for the theory that arthritis deformans may be due to vascular blockage and necrosis of bone underlying articular cartilage.

When the necrotic bone was situated in the diaphyses or in epiphyses away from the articular surfaces, collapse did not occur and there was evidence of some invasion and replacement by new bone, as judged by the presence of irregular cancellous living bone surrounding and even penetrating the persistent areas. Complete replacement of some of the smaller areas had probably come about. But in the case of large areas replacement after advancing to the point of restoring approximately normal strength to the bone, came to a standstill as shown by repeated roentgenographic studies at long intervals, and the fibrous wall about them became more or less extensively calcified and ossified. Small necrotic areas were found, as one in the femoral condyle, invaded by connective tissue and extensively calcified. Scattered calcification also took place to some extent in the large central uninvaded encapsulated areas.

The encapsulated and calcified areas of necrosis in the diaphyses produced characteristic pictures in roentgenograms.

Uncertainty prevails as to whether the necrosis was produced by nitrogen gas obstruction of end arteries of the bones by embolism or by direct pressure on blood vessels and other tissues after liberation from solution in the fat of the bone marrow or in some other unexplained way. The facts that the long bones of the extremities, which are rich in fatty marrow, were the only bones involved, that fat absorbs relatively very large amounts of nitrogen and that nitrogen bubbles would be absorbed slowly from the marrow tissues because of the known sluggishness of the intra-osseous circulation, favor the theory of direct pressure of the gas on vessels and other tissues within the bone. But the extensive involvement of the diaphyses in some cases without involvement of epiphyses, and the involvement of the epiphyses, especially of the head of the femur, without involvement of

diaphyses or without continuity of involved regions in epiphyses and diaphysis are points in favor of infarction produced by nitrogen gas embolism or some other form of intravascular obstruction. Experimental air embolism of the lower limbs of dogs failed to produce bone necrosis.

THE EARLY DIAGNOSIS OF CERVICAL CARCINOMA

ANTHONY WOLLNER, M D , F A C S , New York, New York

THE success of the modern treatment of cervical carcinoma largely depends on the early recognition of the disease. The gratifying results of radiation therapy in cases which come under observation in their early stages therefore make early diagnosis of paramount importance. Cancer propaganda alone, which urges the public to seek medical advice as soon as suspicious symptoms appear, cannot be effective because cervical carcinoma in its early stages is symptomless. How long the cancer may be present before it gives rise to symptoms is unknown. The observations of certain gynecologists (Kermauer, Hinselman, Stahler, and others) that a cervical carcinoma may reach a hopeless stage without producing symptoms, are significant. If it is true that the disease may be in an advanced stage when the first symptoms arise, it is evident that the solution of the problem must involve something more than an appeal to lay women. Nor does more emphasis on the prompt recognition of the early lesion in medical teaching assure definite results. Dietel in Germany studied the histories of a large number of cases of cervical carcinoma and found that in 27 per cent the attending physician was responsible for the delay in treatment, by either failing to recognize the true condition or by neglecting to advise adequate treatment. It is fair to assume that similar conditions prevail in other countries, including this one.

To diagnose a cervical cancer in its symptomless stage may be extremely difficult even for an experienced gynecologist. Carcinoma in its incipency is characterized by minute histological changes, which usually escape recognition, even during the course of a thorough clinical investigation. New diagnostic methods have been perfected in recent years to stimulate interest in the diagnosis of early lesions on the portio. Hinselman devised a colposcope which permits the visualization of

minute details on the portio. This instrument is a valuable contribution to our diagnostic armamentarium, but has limitations which make its universal use impossible. It is expensive, and its application requires considerable time, experience, and skill, even when used by a specialist. Another new diagnostic method, more generally available, is Schiller's iodine test. This is based on the observation that normal squamous epithelial cells contain glycogen, which stains a dark brown color with iodine. Cancer cells possess an excessive glycolytic activity, and therefore do not take the iodine stain. The corollary of this is that areas which remain uncolored after the application of the iodine solution are suspicious of carcinoma. Experience has proved, however, that the iodine paint is by no means a specific test for cancer. It has been found that certain benign changes on the portio may also show a negative staining reaction, and it has been frequently noted that areas which did not stain on one occasion did so on subsequent tests. This observation seems to indicate that the glycogen content of normal cells is subject to physiological variations, probably due to endocrine influences. Despite the fact that the iodine test is not absolutely diagnostic for carcinoma, its application should be encouraged. It is a simple, harmless procedure, which can be universally adopted by the general practitioner and made a part of every routine examination. Such a practice would serve the purpose of focusing the general practitioner's interest on the portio and cervix, and would increase the number of cases referred to specialists for an early definite diagnosis.

At the present time there is no diagnostic method whereby cervical carcinoma can be recognized invariably in its early, symptomless stage. The epidermoid type of cancer often originates in the transition zone, where the squamous epithelium of the portio merges with the columnar epithelium of the cervical mucosa. This area cannot be visualized by inspection through a speculum. When the

From the Department of Gynecology, New York Post-Graduate Hospital. Walter F. Dannreuther, M.D., Director.

Fig 1 Photomicrograph of specimen from cervix in Case 1

lesion becomes evident on the portio, a considerable amount of destruction in the cervix has already taken place. The adenocarcinomatous type of cervical neoplasm presents still greater difficulties in early diagnosis. Fortunately this variety occurs rarely, in about 5 per cent of cases. Adenocarcinoma within the cervical canal may reach an advanced stage without initiating symptoms or being recognizable by inspection or palpation. The introduction of a sound into the cervical canal will be of diagnostic value only in fairly advanced cases. The so called central cervical carcinomas, which originate in the deep structures are hopeless as far as early diagnosis is concerned.

This short review of the diagnostic possibilities in cases of cervical carcinoma demonstrates their relative inadequacy to insure the early recognition of the disease. There is a developmental period in which only a histological examination will reveal the cellular changes which are characteristic of malignancy. Consequently if we hope to make a really early exact diagnosis, biopsy material

must be obtained from cervixes, irrespective of suspicious symptoms.

Three years ago I began a systematic histological study of the cervical mucosa, and my observations were reported in two previous communications (12, 13). In the course of these studies I used two groups of patients. One group consisted of 35 normally menstruating women with apparently normal genitals, and in the histological investigation of the biopsy specimens one case of cervical carcinoma was found, which is reported herewith.

CASE 1. A woman 38 years of age came under observation in 1937. She had been married for 15 years, had one child 14, and had had two miscarriages 12 and 3 years previously. She began to menstruate at the age of 14 years, had normal periods thereafter of two to three days duration with moderate flow. Her chief complaint was cramplike pains in the right lower abdominal quadrant for the past 2 days. The region of the appendix was tender. Gynecological examination revealed moderately descended vaginal walls, a perfectly normal looking cervix, a uterus of normal size and consistency, freely movable, and the adnexa were negative. The patient consented to a cervical biopsy, and the cervical mucosa was removed in its entirety on the eighteenth day after her previous menstruation. The histological examination revealed a small area near the external os which was suggestive of carcinoma.

Figure 1 is the photomicrograph taken of this area. The specimen is partially covered by squamous epithelium. At the point of transition into columnar epithelium, epithelial plugs are seen dipping into the underlying stroma. Beneath the surface three islands are seen which are well defined, surrounded by normal connective tissue. The epithelial cells contained in the islands have hyperchromatic nuclei; some reveal plenty of protoplasm; in others the nuclei fill out the whole cell, indicating irregular mitoses. This histological picture is suggestive of carcinoma, but a definite diagnosis could not be made on the basis of these findings. Serial sections were therefore prepared for a more exacting study. Figure 2 represents the same area in a subsequent section. Several epithelial islands are seen which consist of cells deeper staining than those found in the covering epithelium. Some cells reveal irregular mitoses and show some variations in their size and shape. At the deepest point from the surface some of the islands are broken up into small clumps and become mingled with the surrounding inflammatory cell. This picture demonstrates a beginning malignant invasion in the stroma and fulfills all the requirements for the diagnosis of carcinoma. Figure 3 is a photomicrograph of a further section of the same specimen. It visualizes a full blown cervical carcinoma. Near the surface the classical picture of leucoplakia is seen. In the deeper stroma a dense infiltration by small round

Fig 2 Photomicrograph of a subsequent section obtained in Case 1

Fig 3 Photomicrograph of another later section obtained in Case 1

cells is noted, the epithelial islands are broken up, and there is a deep invasion of the stroma

This case demonstrates a cervical carcinoma in a patient whose genital organs were subjected to a painstaking study and who was found to be gynecologically normal. The carcinomatous lesion was found accidentally in the course of my studies on the normal cervical mucosa. This observation serves as a good example of the problems in early diagnosis. The histological investigation of serial sections permits a tracing of the gradual evolution of the lesion. On and near the surface of the cervical mucosa well defined islands of metaplastic growth were found, and invasion with the earmarks of carcinoma cells was present in the deep tissue, approximately 2 millimeters beneath the surface. It is evident that the development of such a carcinoma requires considerable time before the destructive process reaches the surface, either on the portio or on the endocervix, and becomes grossly visible.

Another group of patients in whom I undertook a systematic histological study of the cer-

vical mucosa consisted of 24 cases in which clinical symptoms of endocervicitis and erosion were present, and in which the following case of carcinoma was found:

CASE 2 A woman 36 years of age came under observation in 1933. At that time she had been married for 14 years and had three children, 9, 7, and 1 years old, respectively. There was no history of abortions. Menstrual periods began at the age of 13 years, recurred regularly every 28 days, were of 4 to 5 days' duration, with profuse flow. Her chief complaint was profuse white leucorrhea and a bearing down sensation. The gynecological examination revealed markedly descended vaginal walls, a lacerated cervix, which was badly eroded, a uterus of normal size, freely movable, and both adnexa negative. On straining a moderate descensus was noted. I advised a diagnostic curettage, conization of the cervix and plastic repair of the pelvic floor, but the patient did not return until 4 years later. Her condition had then become aggravated. The menstrual periods still came at regular intervals, but were prolonged, of 7 to 8 days' duration, and very profuse. The amount of white discharge had increased, and the bearing-down sensation had become painful. On examination, a second degree of cystocele was found. Both lips of the portio were extensively eroded and a

Fig 4 Photomicrograph of specimen removed in Case 7

Fig 5 Area adjacent to that in Figure 4

sticky cervical discharge was present. The uterus was moderately enlarged, firm, in good position, adnexa negative. This time the patient consented to an operation.

Under ether anesthesia dilatation and curettage were performed. A large amount of pale endometrial tissue was obtained. Conization of the cervix and plastic repair of the cystoectocoele were done. The histological examination of the endometrial specimen revealed a marked glandular hyperplasia. Similar findings were noted in the cervical specimen but for a small area near the external os where an incipient carcinoma was found.

Figure 4 demonstrates this area. The portio is covered with normal stratified epithelium which abruptly changes at the transition point where there is a loss of layer formation. The epithelial cells are irregular in size, shape, and staining reaction. The penetrating epithelium separates the cervical glands in some places; in other areas the glands are pushed together and form regular islands in the strand of epithelium. There are places where one finds nests containing typical spindle cells but having no connection with the surface epithelium. Under high power, irregular mitoses can be seen. This photomicrograph presents the histological picture of an incipient malignancy. An adjacent area to that presented here is visualized in Figure 5. A benign invasion of hyperplastic squamous epithelium into the cervical glands is present. The lumen of the glands

is almost completely filled with epithelial cells, transforming some of them into solid islands. A marked proliferation is present in these islands but they are well demarcated, and the individual cells are uniform, not suggesting malignancy. Some of the islands in the deep stroma contain deeper staining cells and occasional irregular mitoses can be seen under high power.

In this case an incipient cervical carcinoma was found, although the clinical picture indicated only a simple erosion with endocervicitis. Both these reported cases of early malignancy have certain features in common which deserve further discussion. In both, the origin of the growth could definitely be placed in the epithelial transition zone. The generally accepted conception, that cervical cancer originates in this area, is supported by these observations. From the viewpoint of early diagnosis, this location is unfortunate. The transition point between squamous and columnar epithelium does not correspond with the clinical designation of the external os. Squamous epithelium sometimes extends far upward in the cervical canal, which places the

transition point beyond the reach of inspection. Furthermore, the lesion's tendency is to penetrate into the deep tissues, consequently, the surface of the endocervix and portio remains intact in the very early stages of the disease. Considering all these facts, it becomes evident that there are neither symptoms nor clinical findings on which to base the diagnosis of cervical carcinoma in the early stage.

Another common feature in both cases is the presence of epithelial metaplastic growths side by side with carcinoma. The interpretation of benign epithelial invasions into the cervical mucosa is a controversial matter. Ribbert in his *Textbook of Pathology*, which was published in 1896, discussing cervical carcinomas, stated that benign epithelial metaplasia is the basis on which carcinoma develops through atypical cell divisions. This conception was widely accepted at that time, and among others, von Franque in 1907 considered leucoplasias as precancerous lesions. Subsequent investigators, however, discarded Ribbert's theory. The now generally accepted view was expressed by Robert Meyer, who believes that epithelial metaplasia is the manifestation of a healing process in erosions. The squamous epithelium growing back to the denuded surface, in its proliferation surrounds and invades the ducts of the glands. This invasion may extend to the deeper layer of the mucosa and some glands may be filled out entirely with squamous epithelial cells. Meyer also believes that these invasive growths eventually become displaced to the surface, where they belong, after the healing process is completed. Recently Hinselman, who made an extensive study of leucoplasias, expressed the opinion that carcinoma cannot develop without a preliminary stage such as leucoplacia.

My observations do not seem to substantiate the conception that epithelial metaplasia is a healing process in the cervical mucosa. In 24 cases of marked erosion I subjected the endocervix to a painstaking histological study. In only 3 instances could I find an evidence of epithelial metaplasia in the specimens. If the healing process were the etiological factor for these benign growths, one would expect the histological picture of epithelial metaplasia to be present in almost every case of erosion.

Recent observations that the biological functions of the cells in the cervical mucosa are under hormonal influences, a fact clearly demonstrated in my previous studies, place the interpretation of metaplastic growths on a new basis. In animal experimentations it has been shown by several investigators (Selye, Thompson and Collip, Overholser and Allen; Engle and Smith, and others) that prolonged administration of follicular hormones exerts a specific stimulation on the epithelial cells of the cervical mucosa. Herold and Effkeman experimented with rats. After the administration of follicular hormones, they observed the crowding out of the normal columnar epithelial linings of the glands by squamous epithelium. After 3 months' treatment some glands were found to be entirely filled with squamous epithelium and conveyed the impression of isolated islands beneath the surface. In castrated rats the epithelial metaplasia occurred after a shorter period of treatment than in normal animals.

In a castrated woman I followed up the histological changes in the cervical mucosa during the administration of estrone, and observed changes in the human cervix identical with those reported in animals. I was able to produce epithelial metaplasia in the human endocervix by prolonged hormone administration, and the disappearance of the metaplastic growths was noted after discontinuance of the hormone therapy. A detailed report of my observations in this case will be made at a later date.

Data are accumulating which prove that epithelial metaplasia in the cervical mucosa is the result of excessive hormonal stimulation. It is of interest to ascertain in the case herein reported whether the histological picture of the endometrial specimen substantiates this contention. We know that excessive follicular hormone production is expressed in the endometrial histology by the production of hyperplasia. An endometrial specimen (Fig 6) was obtained in Case 2, which case incidentally revealed the most pronounced metaplastic changes in the cervical mucosa. The photomicrograph shows the typical picture of glandular hyperplasia. Portions of the cervical mucosa outside the areas of carcinoma reveal

Fig 4 Photomicrograph of specimen removed in Case 2

Fig 5 Area adjacent to that in Figure 4

sticky cervical discharge was present. The uterus was moderately enlarged, firm, in good position, adnexa negative. This time the patient consented to an operation.

Under ether anesthesia dilatation and curettage were performed. A large amount of pale endometrial tissue was obtained. Conization of the cervix and plastic repair of the cystocele were done. The histological examination of the endometrial specimen revealed a marked glandular hyperplasia. Similar findings were noted in the cervical specimen but for a small area near the external os where an incipient carcinoma was found.

Figure 4 demonstrates this area. The portion is covered with normal stratified epithelium which abruptly changes at the transition point where there is a loss of layer formation. The epithelial cells are irregular in size, shape, and staining reaction. The penetrating epithelium separates the cervical glands in some places; in other areas the glands are pushed together and form regular islands in the strand of epithelium. There are places where one finds nests containing typical spindle cells but having no connection with the surface epithelium. Under high power, irregular mitoses can be seen. This photomicrograph presents the histological picture of an incipient malignancy. An adjacent area to that presented here is visualized in Figure 5. A benign invasion of hyperplastic squamous epithelium into the cervical glands is present. The lumen of the glands

is almost completely filled with epithelial cells, transforming some of them into solid islands. A marked proliferation is present in these islands, but they are well demarcated, and the individual cells are uniform, not suggesting malignancy. Some of the islands in the deep stroma contain deeper staining cells and occasional irregular mitoses can be seen under high power.

In this case an incipient cervical carcinoma was found, although the clinical picture indicated only a simple erosion with endocervicitis. Both these reported cases of early malignancy have certain features in common which deserve further discussion. In both the origin of the growth could definitely be placed in the epithelial transition zone. The generally accepted conception that cervical cancer originates in this area is supported by these observations. From the viewpoint of early diagnosis, this location is unfortunate. The transition point between squamous and columnar epithelium does not correspond with the clinical designation of the external os. Squamous epithelium sometimes extends far upward in the cervical canal, which places the

apparently removed all of the malignant growth

IMPORTANCE OF EARLY DIAGNOSIS, METHODS OF OBTAINING BIOPSY SPECIMENS

An early diagnosis of cervical carcinoma is of twofold importance. Of prime importance are the clinical considerations, because early cases yield to irradiation therapy in a gratifying manner, and a cure can be anticipated in a majority of them. There are indications to warrant the hope that in incipient cases a radical excision of the cervical mucosa alone may eradicate the neoplastic process. A case may be regarded as incipient so long as it remains symptomless and clinically unrecognizable, although the diagnosis may be made from histological findings. From a clinical standpoint, it is highly desirable that cervical carcinoma shall be detected and extirpated in its incipency.

The other factor which makes an early diagnosis of paramount importance is the scientific aspect of the problem. We cannot hope to solve the cancer problem without acquiring exact knowledge of the histological genesis of carcinoma in the human. At the present time there is no clean cut histological definition of carcinoma. Some pathologists consider variations in the size, shape, and staining qualities of the epithelial cells and atypical mitotic figures as carcinomatous, while others are reluctant to make a definite diagnosis of carcinoma unless malignant invasion into the stroma is present. Whether carcinoma is the result of gradual changes in the biological function of the cells is a moot question. It is difficult to draw a sharp line of demarcation between a benign atypical epithelial proliferation and carcinoma. It is logical to assume, however, that if the histological study of a sufficiently large number of incipient cases were possible these questions might be solved eventually. The uterine cervix is an ideal site for such an investigation, as it is easily accessible and permits the taking of biopsies without serious discomfort and unpleasant sequelæ to the patient.

It is unfortunate that the diagnostic histological exploration of the cervical mucosa has not had the attention it deserves. This is particularly true because this structure is the

most common site of pathological lesions in the female genital tract. Ninety per cent of uterine carcinomas originate in the cervix. Furthermore, in gynecological practice a normal looking cervix is unusual. Considering these facts, it seems reasonable that the endocervix as a histological unit should receive as much attention as the uterine lining membrane, the endometrium. In the many routine diagnostic curettages the endocervix is hardly, if ever, touched. It must be remembered that a simple scraping of the endocervix with a curette does not provide sufficient tissue for a histological diagnosis. As I pointed out in my previous studies, due to the peculiar anatomical structure of the cervical mucosa, adequate tissue material can be obtained only by excision. For this purpose I have employed the Hyams' conization method (5) during the past 5 years in nearly two hundred cases, and have never observed any untoward after-effects. If conization is done after dilatation and curettage, it does not add to the discomfort of the patient and does not prolong hospitalization. Routine removal of the cervical mucosa for histological examination should be regarded as a logical procedure in cases in which a diagnostic curettage is indicated.

Cervical pathology is not necessarily manifested by symptoms which would indicate a diagnostic curettage. It has been shown by my 2 cases that the most destructive lesion of all, carcinoma, may develop in a symptomless cervix. The limited number of extremely early cases reported elsewhere in the literature were also found accidentally. Evidently, if a beginning cervical carcinoma is to be discovered in any large number of cases, a routine procedure must be adopted in office gynecology, which permits the taking of cervical biopsies, irrespective of the absence of suspicious symptoms. A method is available, which by its simplicity and safety deserves to be included in our diagnostic armamentarium. For diagnostic purposes it is not necessary to remove the cervical mucosa throughout its entire length, since sufficient observations have proved that cervical carcinoma originates in the lower half of the canal. No early case has been found in the literature to indicate a higher point of origin. I designed cutting wires for coning out

Fig 6 An endometrial specimen Case 2

Fig 7 Cervical specimen showing markedly dilated glands with preserved epithelial lining

histological changes similar to those found in the endometrium. Figure 7 visualizes the cervical specimen in which numerous markedly dilated glands with well preserved epithelial lining are seen. The picture very much resembles that found in hyperplastic endometria, called the 'Swiss cheese pattern'. The histological study of both the endometrial and cervical specimens reveals changes which are known to be the result of excessive estrone influence.

In the histological diagnosis of early cervical carcinomas epithelial metaplasia merits special attention. Whenever such a benign epithelial invasion is discovered, it is advisable to subject the specimen to a thorough study by making serial sections. In my 2 cases a gradual transformation of benign epithelial hypertrophy into malignancy was noted. There is a strong indication that epithelial metaplasia developing under hormonal influence constitutes the basis on which carcinoma originates because of the added stimulus. There really is little difference between carcinoma cells and the normal epithelium. The difference lies

chiefly in an altered biological activity, manifested by rapid proliferation. We know that estrone governs the normal proliferation of the epithelial cells and that its continuous action produces benign epithelial invasions into the glands which invasion however is orderly never penetrating into the surrounding stroma. The factor which adds the stimulus for unorganized destructive, invasive growths has not yet been found.

The clinical course of my 2 reported cases deserves to be mentioned. After having established the diagnosis of carcinoma, no further treatment was given these patients. Both of them are regularly reporting for a gynecological follow up. The first patient has now been observed for 24 months and the second for 22 months, since the diagnosis of carcinoma was established. Both patients are well, and repeated careful examinations fail to reveal any sign of a lesion in the genital tract. The elapsed time is too short to justify a final opinion, but the implications are that the simple radical excision of the cervical mucosa

EARLY PHASES OF PROSTATIC HYPERPLASIA

CLYDE L. DEMING, B A , M D , F A C S , and CHARLES NEUMANN, M D ,
New Haven, Connecticut

MANY theories have been proposed by men interested in the various branches of medicine to explain the development of benign prostatic enlargement in man. An extensive study of the gross and microscopic lesions has been made, but insufficient attention has been given to the early phases of the enlargement. The urologist frequently observes that the benign enlargement of the prostatic gland, which he sees at operation, is covered by a thin layer of posterior urethral epithelium. In many instances, the tumor seems to replace most of the prostatic gland. There is full agreement with regard to the histological constituents of the surgical specimens. They are composed of glandular, fibrous, and muscular tissues, but the relative amounts of these tissues are variable. The fact that there is a preponderance of the glandular tissue has led investigators to presuppose that the enlargements are mainly glandular in origin. The wide distribution of the glandular nodules in the various lobes of the prostate is further evidence in support of this theory. One of the outstanding declamations is that of Marion and Zuckerkandl, who believed that these enlargements begin in the glands of Albarran Velpéau, as early as 1841, recognized fibromuscular masses. Thompson, in 1873, was inclined to believe that the primary tumors bear some resemblance to early uterine myomas. As late as 1929, Kausch, in Germany, suggested that the glandular elements are derived from the deep urethral glands. Keyes, Hinman, and Randall adduce evidence from the material studied to show that most of the foregoing theories of early development of "prostatic hypertrophy" are justifiable.

It is necessary to have more definite knowledge concerning the early anatomical phases of benign prostatic enlargement before its

cause can be logically established. It is the object of this paper to attempt to throw more light on the first and foremost part of the problem, namely, the beginnings of the so called prostatic hypertrophy. In the prostatic glands which we see at the operating table, so much disorientation of the components of the organ has been produced by growth, pressure, and atrophy that little information is to be obtained from a study of them. The basis for consideration of the early anatomical lesions of the so called prostatic hypertrophy is the study of anatomical specimens of prostates obtained at autopsy from subjects 45 years of age and upward. From the microscopic study of minute, early lesions one can hope to show where and how the lesion originates.

The specimens were fixed in 10 per cent formalin solution and cut transversely at five different levels. When small nodules were discovered, either with the naked eye or by microscopic study, serial sections were cut of the entire transverse section involved, and the nodule or nodules were followed up and down the prostate to their terminations. Various stains were used, but the hematoxylin-eosin and Masson trichrome stains have proved the most satisfactory, the latter being employed to differentiate muscle from fibrous tissue. The large and complete sections were first studied by throwing the entire section on the screen with the projectoscope. This gave an opportunity for comprehensive study of the architecture of the gland as a whole which it is impossible to obtain by the use of the microscope. For minute, localized detail of the sections, the microscope played its part.

From 150 specimens, 24 prostates with sufficiently early lesions have been studied. The specimens contain aglandular and glandular areas in various stages of development. In most of the specimens the two lesions exist together, in 6 only aglandular masses are found, in none of the specimens do glandular nodules exist without aglandular areas.

From the Departments of Surgery and Pathology, New Haven Hospital, and Yale University

Read at the annual meeting of the American Association of Genito-Urinary Surgeons, Absecon, New Jersey, May 2-4, 1938

Fig 8 A wire used in nulliparæ B in lacerated cervixes C instrument in application

the lower half of the endocervix, which differ from the Hyams conization wires in their size and shape. They are three quarters of an inch long and are constructed in two different shapes. Figure 8 depicts the electrodes. A the wire used in nulliparæ and B in lacerated cervixes, whereas C shows the motion by which the specimen is obtained. Employing this method the area near the internal os is avoided, thereby causing less discomfort to the patient, as this region is the most sensitive part of the cervical canal. The circular excision is completed in a few seconds and can be done without anesthesia. The excised specimen is placed in formalin solution for subsequent histological study. The denuded area does not require after treatments, and re-epithelialization is complete after 3 weeks, without scar tissue formation or subsequent stenosis.

SUMMARY

The present study is based on 59 cases in which a routine removal of the cervical mucosa was done for purposes of a systematic histological investigation. Although none of these

cases revealed symptoms or clinical findings which indicated malignancy, in 2 patients definite cervical carcinoma was found. In both cases a simple excision of the endocervix apparently effected a cure. My experiences justify the following recommendations: (1) No diagnostic curettage should be considered complete without removal and histological examination of the cervical mucosa. After dilatation and curettage the Hyams conization offers the simplest and safest way to accomplish this purpose. (2) Every woman past her thirtieth year should be considered a potential candidate for cervical carcinoma. It is advisable for patients in this age group to have at least one routine tissue examination of the lower half of the cervical mucosa. The only contraindication for this procedure is inflammation or tenderness in the adnexa.

I believe that in the present cancer-conscious era it should not be difficult to impress our patients with the advantages of a routine cervical biopsy. Gynecologists who adopt these two recommendations, may be rewarded by the gratifying experience of recognizing and curing an occasional patient with incipient cervical carcinoma. The accumulating histological studies on the lower half of the cervical canal will contribute greatly to a better understanding of the physiological function of a structure which is a common site of carcinoma.

duct These epithelial buds may enter the solid nodule laterally or centripetally and form glands Because the glands grow more rapidly than the muscle and collagenous tissue, they may entirely replace the muscle tissue and cause the nodule to appear wholly glandular As the peripheral muscle tissue becomes compressed, it forms the "surgical capsule" of the glandular mass This method of glandular tissue formation from ducts is similar to that seen in the normal embryological budding from the posterior urethra, which forms the anlage of the prostatic glands This process may be a re-awakening of the activity possessed by these ducts during the embryological period One can readily demonstrate this epithelial response on the inside of a duct adjacent to an aglandular nodule, while directly across its lumen the epithelium is dormant (Figs 4 and 5)

In this study, glandular nodules have not been found in the lateral and posterior lobes of the prostate Aglandular nodules have been seen in the roof of the urethra and below the crista urethralis, from which hyperplastic lobes could theoretically develop The ante-

rior and middle hyperplastic lobes have not been studied, nor have we found the reason for the occurrence of an isolated glandular lobule within the bladder at some distance from the prostate and not connected with it A continuation of these studies should undoubtedly reveal these mysteries

Since the glandular component of the prostatic hyperplasia is seen to be derived from the prostatic ducts within the urethral muscular wall, one would like to analyze further the origin of the aglandular nodules The fibromuscular nodules of the prostate resemble histologically the fibromyomas of the uterus (Fig 6) The uterine tumor has been shown to develop from a muscle cell The sinus utricularis is the homologue of the uterus and hence of muellerian duct origin The work of Lowsley, Walker, and others on the embryology of the prostate and urethra discloses the fact that the muscle fibers of the lower muellerian duct system meet the muscle fibers of the wolffian duct system in the posterior urethra and intertwine themselves with the muscles which come down from the ureters, trigone, and bladder The largest number of solid muscular nodules is found near the utricle and below its floor (Fig 7) The aglandular, fibromuscular tumors

Fig 1 Photomicrograph of prostate of man aged 72 years. Section near verumontanum showing fibromuscular nodule near urethra. $\times 2$

The aglandular areas are found within the musculature of the urethral wall. They may be single (Fig 1) but are more often multiple and bilateral, located anywhere within the musculature of the urethral wall between the external and internal sphincters. As they develop in size, they tend to become round and oblong in shape and may later become quite large and encapsulated. As the result of localized outgrowths or of the union of two or more of the developing centers, they may assume a nodular appearance. That these aglandular nodules develop to a size sufficient

Fig 2 Photomicrograph of prostate of man aged 68 years showing glandular nodule in lateral portion of muscular urethral wall. Glandular nodule in lateral portion of muscular urethral wall. Glandular nodule contains heavy muscular stroma. $\times 1\frac{1}{2}$

to cause urinary obstruction has been well demonstrated by Hinman and Sullivan, Mitchell and Blaisdell, and Vescen. In the routine histological examination of surgical prostatic specimens, it is not uncommon to find masses of solid tissue and even definite encapsulated aglandular nodules in the presence of glandular nodules. Patch and Rhea found that 25.4 per cent of 181 consecutive surgical specimens of so-called prostatic hypertrophy showed leiomyomatous nodules varying in size from 0.5 to 3.0 millimeters.

The glandular nodules vary in size and are surrounded by circular muscle fibers (Fig 2). The acini within a nodule may show active budding projections and dilated cystic areas. Cystic dilatations may appear early, but corpora amylacea are not seen in the early lesions. The glandular nodules are found in the muscular wall of the urethra (Fig 3) and have not been seen in the lateral and posterior lobes. When these nodules increase in size they deflect the urethra greatly, compress the true lateral and posterior lobes, and appear as lateral lobes on either side of the urethra. They apparently do not develop from the suburethral glands of Albarran, as was formerly thought.

The study of serial sections has led the authors to believe that the glandular nodules are a result of the invasion of an aglandular nodule by epithelial buds from an adjacent

Fig 3 Photomicrograph of prostate of man aged 74 years showing bilateral tumors. A a fibromuscular nodule half invaded by glands. B a small glandular nodule on opposite side. $\times 1\frac{1}{2}$

in dogs and rats As far as the authors are aware, no one has ever demonstrated a pathological benign prostatic enlargement in dog, rodent, monkey, or horse which caused retention of urine, nor has such a lesion been produced experimentally in animals All of the experimentally produced prostatic enlargements are physiological hypertrophies, not tumors or hyperplasias We must not confuse them with the pathological lesion in man The natural prostatic enlargement in the old dog compares histologically with the experimental enlargement produced by testicular hormonal injections It can be reduced by removal of the testicular hormone or by castration of the dog Castration in man has failed to show any effect on the pathological prostatic enlargement The fact that benign pathological enlargement of the prostate has been found in eunuchs leads one to minimize the part played by the testicle in its development

Rothschild, Greene, and Brooks believed prostatic enlargement to be the result of inflammation, as suggested by Ciechanowski, but Cabot and Smith have clearly demonstrated that men with histories of infection are less likely to develop a "prostatic hypertrophy" Prostatic enlargement is not due to arteriosclerotic changes, because it occurs in individuals who do not have arteriosclerosis Reischauer's theory of compensatory hypertrophy is illogical Kausch has correctly ruled out the adenoma theory, because the growth does not fulfill the criteria enunciated for adenomas We have shown that the enlargement does not begin in glands, nor is it necessarily derived from glands If it were derived from the musculature around a duct or gland, the primary nodule would show a duct or gland within its center This has not been shown in our observations

SUMMARY

This work definitely discloses that the early change of benign enlargement of the prostate in man is primarily a multiplication of fibromuscular elements It resembles in its early stages the uterine fibromyoma, which is derived from a muscle cell of the uterus Since the posterior urethra and the internal vesical

sphincter contain muscle fibers which are derived from the same embryological building material as that of the uterus, it is fair to assume that these two tumors have the same origin We do not agree wholly with Adrion that the glandular portion of the tumor is necessarily derived from glands but believe that it has its origin in ducts adjacent to the fibromyomatous nodule The suburethral glands of Albarran are not involved in early lesions It is probable that the solid nodule produces some stimulating and proliferating effect upon the epithelium of the duct wall, causing the epithelium to invade the solid nodule and form glands within it The fibromyomatous tissue is invaded and overgrown by a more rapidly growing duct and glandular tissue, with the result that the nodule in its later stages develops the appearance of an encapsulated glandular tumor Benign prostatic enlargements are not hypertrophies but are true hyperplasias, derived from muscle, fibrous tissue, and ducts

Recognition is made of the assistance of Dr. Dan S. Egbert and of Dr. Hyman A. Weiner in the early part of this study Appreciation is also expressed to Mrs. Ethel Kober for the preparation and mounting of the histological sections

The greater part of this work was made possible by an anonymous gift and by a grant from the Fluid Research Fund of Yale University

nodule depends on whether or not the primary nodule is invaded by the epithelium of an adjacent duct.

Further evidence to support the hypothesis that these tumors of the prostate arise from the vestigial component of the muellerian system may be elicited from a consideration of activity produced in homologous vestigial organs by hormones. In the dog all the prostatic glands are derived from the epithelium of the utricle, which is very sensitive to estrin (Zuckerman). In rodents and the rhesus monkey part of the glands of the prostate take their origin from the urethral buds and part from the sinus epithelium, while in man all of the prostatic glands have been shown to originate from urethral epithelial buds. Further study along this line should add materially to the practical issues involved in tissue reactions to hormones.

THE ANATOMY OF THE PELVIC AND UROGENITAL DIAPHRAGMS, IN RELATION TO URETHROCELE AND CYSTOCELE

ARTHUR H CURTIS, M D , F A C S . , BARRY J. ANSON, Ph D (Med Sc), and
CHESTER B McVAY, M S , M D , Chicago, Illinois

IN the course of a re-study of the female pelvis and perineum, certain controversial anatomical features of gynecological importance remained undetermined after our concerted attack from the combined viewpoints of the anatomist and the gynecologist, despite painstaking dissection of the pelvis of five selected female bodies, a sixth dissection, this time from within the pelvis, displayed the anatomical relationships so effectively that we are impelled to present our observations and clinical deductions¹ The three accompanying illustrations by Tom Jones are life-size² drawings made from the actual dissections

PERITONEUM AND EXTRAPERITONEAL (CELLULAR) TISSUE

Within the pelvis of the present specimen, and in the manner regularly described, the parietal peritoneum of the abdominal cavity proper is carried downward into the pelvic subdivision of the cavity, where it is draped over the contained viscera, adapting itself to the inequalities produced by them³ This peritoneum is at an appreciably higher level than the parietal fascia which covers the pelvic floor (the superior fascia of the pelvic diaphragm) There is thus created a considerable

subserous space between the peritoneum and the fascia, this is filled with an adipose areolar tissue, through which course the visceral nerves and vessels⁴

The features of anatomy described are corroborative of those found in the usual descriptions of the female pelvis With them the present study is not particularly concerned, our interest being centered in the diaphragmatic structures upon which the pelvic organs rest, and their tubular reflections, which, ascending upon the organs, form strong musculo-fibrous investments

ENDOPELVIC FASCIA

A firm fascia covers the pelvic floor, this is the superior fascia of the pelvic diaphragm (Fig 1), the endopelvic fascia is that portion which is reflected from the floor upward upon the viscera The manner of reflection for the bladder is different from that for the rectum and vagina (Fig 1) An aponeuroticofascial ridge sweeps forward from the region of the spine of the ischium, and soon divides into an inferior fascial arch, the white line, and the somewhat more superiorly placed, slightly curved arcuate ligament. At the lateral wall of the bladder the fascial arch (the white line) is a wing-like elevation standing away from the pelvic wall, the abundant cellular tissue is easily removable from it Each wing divides to pass in front of and behind the bladder, thus forming a fascial tube for that organ The urethra is covered anteriorly with the endopelvic fascia, but laterally, the fascia is stretched from the pelvic wall to the bladder above the level of the urethra

The fascial tubes of the endopelvic fascia for the vagina and the rectum are reflected

From the Department of Obstetrics and Gynecology and the Department of Anatomy (contribution no 277), Northwestern University Medical School Presented, in part, at the San Francisco meeting of the American Medical Association (J Am M Ass, 1938, 111 903)

¹The subject was a negress, 20 years of age, 5 feet 3 inches tall, weight 72 pounds (after embalming) The pelvis and perineum were completely free from gross pathology, the arteries were unusually well injected It is the authors' belief that such a report upon serial dissections of a completely normal subject should be helpful to the gynecologist, stylized portrayals are common conventionalized descriptions thereof equally abundant It is planned to extend this study as rapidly as suitable specimens become available

²The plates have been reduced to five-eighths actual size

Fig 2 The fascial layers illustrated in Figure 1 have been removed and the viscera excised to a lower level, in order to demonstrate the muscular constituents of the pelvic floor and the relations of these to the viscera. The urethra has been pulled aside to show the course of the levator fibers on its posterior aspect and the nature of the "pubourethral ligament," indicated by an asterisk

upper border is arching, convex on its superior edge, this line of attachment coinciding at the summit of the convexity with the edge of the obturator foramen at the position of the obturator canal

This anterior portion of the levator ani inserts not only into the coccyx but also into the urethra, the vagina, and the rectum, the rectal portion is broadest, the vaginal insertion is two-thirds as wide as the rectal, and but few fibers enter the urethra, these upon its posterolateral aspect

The fibers of the muscle which pass to the vagina ascend for a short distance upon the vagina, then lose themselves in the intrinsic musculature of the organ

These important visceral relations of the pubococcygeal muscle are neglected features in the textbooks of anatomy which students and practitioners customarily consult, no mention has heretofore been made of the rela-

tions of the muscle bundles to the urethra, that which has been offered regarding their relation to the vagina and the rectum is incorrect

Thus, Gray (1936) states that the pubococcygeus is directed backward along the side of the anal canal on the way to a coccygeal attachment; according to Cunningham (1937) the medial part of this muscle (termed puborectalis) sweeps backward over the side of the vagina and the rectum, the muscles of the two sides meeting dorsally to form a sling for the anorectal junction. This concept is repeated in Morris (1933), the statement being made that the fiber bundles course past the urogenital organs and the rectum on each side. According to Spalteholz (1930) a few fibers are sent into the wall of the rectum, Piersol (1930) similarly describes an insertion of pubococcygeal fibers into the lower part of the rectum.

tion of the band the muscle arises from the spine of the ischium, but as far as can be determined by palpation only the three or four posterior fascicles actually arise from the bone. The band as a whole can be readily separated almost throughout its length from the adjacent margin of the coccygeus muscle. Its insertion is entirely bony; no fibers enter the walls of the pelvic organs.

3 *Coccygeus* (Figs 2 and 3) The plane of the flat surface of the coccygeus lies at almost right angles to that of the iliococcygeus.¹ In the region of the ischial spine the separate fascicles are very evident, but medially the surface is smooth and tendinous rather than muscular. The muscle at its coccygeal insertion is excessively thin. It is aponeurotic at its insertion, and almost entirely aponeurotic along its posterior margin.

THE UROGENITAL DIAPHRAGM

The superior fascia of the urogenital diaphragm, in relation to the urethra, is not a smooth plane, being elevated at the lateral margins of the urethra to a height of 0.8 centimeter above the floor proper (Fig. 2). This paired structure is a miniature counterpart of the uterosacral ligaments. Arising from the pubic bone it forms bilateral bands which narrow somewhat, then spread out upon reaching the urethral wall. Posteriorly, in ascending from the pelvic floor, they are smooth, but anteriorly they are set off from the pelvic floor and elevated in the form of wing-like margins. Together the wings, which might well be called *pu o-urethral ligaments*, bound a tiny cul-de-sac through which the perineal veins communicate with the pelvic venous plexus (removed in the dissections), this cul-de-sac, oval in outline, is 1.5 centimeters wide, 0.8 centimeter long (with the urethra retracted

posteriorly). These ligamentous wings correspond in position to the transverse ligament of the pelvis but they are more than simply the fused fascial layers of the urogenital diaphragm, since within each is included a band of muscle fibers. They ascend on the lateral walls of the urethra for a distance of 0.6 cm., the skeletal fibers becoming lost among those of its intrinsic musculature (Fig. 3).² Here, again, as in the relationships of the levator to the organs, current descriptions have been found to be inadequate.

The urogenital diaphragm (triangular ligament) as a whole, situated below and in front of the pelvic diaphragm, completes the pelvic support, arising from the inferior ischiopubic ramus, this musculomembranous shelf stretches across the anterior one third of the pelvic outlet at a right angle to the long axis of the vaginal canal. The muscles of the urogenital diaphragm constitute the external sphincter of the urethra in the male, but in the female they are also closely related to the vagina and the urethra. The muscle fibers course chiefly in a transverse direction, toward the midline. Encountering the tubular organs, they insert firmly into their walls (Fig. 3).

As described, bilateral bands of muscle bundles ascend, wing-like, upon the urethra, clothed by the superior fascial layer of the diaphragm. Between the urethra and the vagina only a slight interval exists, through which a few fibers of the sphincter interdigitate with those from the opposite side of the perineum. The bulk of the muscle fibers of the so called sphincter of the urethra actually terminates in the wall of the vagina, as does the musculature of the levator ani. The space between the vagina and the rectum is again so narrow that fibers can scarcely be traced across the midline at that point. The most posteriorly placed muscle fibers of the urogenital diaphragm do not terminate as muscle fascicles in the wall of the rectum, rather it would seem that there are aponeurotic extensions to the rectum of those muscle fibers

¹The coccygeus muscle is 2.4 centimeters wide at its origin, 4.0 centimeters in width at the insertion, at this extremity the aponeurosis attaching the muscle to coccyx is exceedingly thin, measuring slightly less than 0.1 centimeter in thickness. Since the only important difference structurally between the iliococcygeus and the coccygeus is in the character of the origin, the present terminology would seem to be illogical. While one muscle arises principally from tendon and the other from bone, both insert into the coccyx or coccygeus, as it now is (since its tendinous origin is iliac), whereas the latter should be called ischio-coccygeus, because its insertion sets it off from the other two portions, it really should be included with them as one of the constituents of the pelvic diaphragm. The fact that the coccyx is wide proximally and therefore fills a greater portion of the pelvic opening should make no difference in the scheme of naming these two muscles. So far as can be judged from the specimen, the origin of the coccygeus takes place from the very margin of the ischium just above the spine and from the posterior border of the spine itself.

²That part of the urethral sphincter muscle which ends in the vagina is 1.3 centimeters wide, that which terminates in the urethra is exactly half that width. The pelvic urethra, which would correspond to the prostatic portion of the male, is 2.5 centimeters in length. The urethra measures 1.4 centimeters in the transverse direction, 0.8 centimeter in the sagittal. It is apparent from probing its lumen that an appreciable dilatation occurs between the internal meatus and the level of the urogenital diaphragm.

Fig 3 The musculature of the left side remains the same as in Figure 2. The urethra has been cut down to within 1.4 centimeters of the urogenital diaphragm. The right half of the vagina has been cut to a level corresponding to that of the superior surface of the urogenital diaphragm; on the left it remains as in the preceding figure. On the right the pubococcygeal portion of the pelvic diaphragm has been removed and the ilio coccygeal portion has been retracted to show the gluteus maximus muscle. From the ischioanal fossa all of the fatty tissue has been removed to expose the inner surface of the perineal integument. The musculature of the urogenital diaphragm (the urethral sphincter) is revealed by the removal of the superior fascia; additionally the pudendal artery and its branches are shown as they pass from Alcock's canal to the viscera and urogenital diaphragm; the veins have been excised.

It is evident from the foregoing that no standard work on anatomy presents a description of pelvic structure which meets the requirements of present day gynecology.

As in the case with the vaginal part, the muscle fibers of the rectal subdivision of the pubococcygeus are lost in the intrinsic coat; the small muscle bundles became tendinous and insinuate themselves into the space between the longitudinal and circular coats of intrinsic musculature there interdigitating with the fibers of smooth muscle. Between these interdigitating muscle bundles there occur definite hiatuses through which pass small hemorrhoidal vessels; with the unaided eye at least five of these can be seen (vessels have been removed in the dissections so that only spaces are seen in Figs. 2 and 3).

The part of the entire pubococcygeus which inserts chiefly into the coccyx resembles a true

subdivision, since between it and that portion which terminates in the rectal wall a cleft exists along two thirds the length of the adjacent margin—the cleft interrupted midway by an exchange of muscle fibers across the hiatus. The cleft is prominent at its medial end, since there it is bounded posteriorly by fibers which pass to a deeper part of the rectum. The insertion of the hinder part is covered by a ligamentous band which takes the place of the expected rectococcygeus muscle.

2. Iliococcygeus. This posterior or iliac part of the levator ani at its origin is chiefly tendinous (Figs. 2 and 3).¹ The border is concave superiorly; the combined origin of the ilio coccygeus and pubococcygeus describing an S shaped curve. At the extreme posterior por-

¹The ilio coccygeus muscle is 3.5 cm. in width at its origin; it tapers to 1.5 cm. at its coccygeal insertion (of which it is approximately 0.8 cm. from the coccyx) and is joined by the pubococcygeus.

tion of the band the muscle arises from the spine of the ischium; but as far as can be determined by palpation only the three or four posterior fascicles actually arise from the bone. The band as a whole can be readily separated almost throughout its length from the adjacent margin of the coccygeus muscle. Its insertion is entirely bony, no fibers enter the walls of the pelvic organs.

3 *Coccygeus* (Figs 2 and 3) The plane of the flat surface of the coccygeus lies at almost right angles to that of the iliococcygeus¹. In the region of the ischial spine the separate fascicles are very evident, but medially the surface is smooth and tendinous rather than muscular. The muscle at its coccygeal insertion is excessively thin. It is aponeurotic at its insertion, and almost entirely aponeurotic along its posterior margin.

THE UROGENITAL DIAPHRAGM

The superior fascia of the urogenital diaphragm, in relation to the urethra, is not a smooth plane, being elevated at the lateral margins of the urethra to a height of 0.8 centimeter above the floor proper (Fig 2). This paired structure is a miniature counterpart of the uterosacral ligaments. Arising from the pubic bone it forms bilateral bands which narrow somewhat, then spread out upon reaching the urethral wall. Posteriorly, in ascending from the pelvic floor, they are smooth, but anteriorly they are set off from the pelvic floor and elevated in the form of wing-like margins. Together the wings, which might well be called *pu o-urethral ligaments*, bound a tiny cul-de-sac through which the perineal veins communicate with the pelvic venous plexus (removed in the dissections), this cul-de-sac, oval in outline, is 1.5 centimeters wide, 0.8 centimeter long (with the urethra retracted

¹The coccygeus muscle is 2.4 centimeters wide at its origin, 4.0 centimeters in width at the insertion, at this extremity the aponeurosis attaching the muscle to coccyx is exceedingly thin, measuring slightly less than 0.1 centimeter in thickness. Since the only important difference structurally between the iliococcygeus and the coccygeus is in the character of the origin, the present terminology would seem to be illogical. While one muscle arises principally from tendon and the other from bone, both insert into the coccyx or coccyx and sacrum. It would seem that the former should be termed iliococcygeus, as it now is (since its tendinous origin is iliac), whereas the latter should be called ischio-coccygeus, because its insertion sets it off from the other two portions; it really should be included with them as one of the constituents of the pelvic diaphragm. The fact that the coccyx is wide proximally, and therefore fills a greater portion of the pelvic opening should make no difference in the scheme of naming these two muscles. So far as can be judged from the specimen, the origin of the coccygeus takes place from the very margin of the ischium just above the spine and from the posterior border of the spine itself.

posteriorly). These ligamentous wings correspond in position to the transverse ligament of the pelvis but they are more than simply the fused fascial layers of the urogenital diaphragm, since within each is included a band of muscle fibers. They ascend on the lateral walls of the urethra for a distance of 0.6 cm., the skeletal fibers becoming lost among those of its intrinsic musculature (Fig 3)². Here, again, as in the relationships of the levator to the organs, current descriptions have been found to be inadequate.

The urogenital diaphragm (triangular ligament) as a whole, situated below and in front of the pelvic diaphragm, completes the pelvic support, arising from the inferior ischiopubic rami, this musculomembranous shelf stretches across the anterior one third of the pelvic outlet at a right angle to the long axis of the vaginal canal. The muscles of the urogenital diaphragm constitute the external sphincter of the urethra in the male, but in the female they are also closely related to the vagina and the urethra. The muscle fibers course chiefly in a transverse direction, toward the midline. Encountering the tubular organs, they insert firmly into their walls (Fig 3).

As described, bilateral bands of muscle bundles ascend, wing-like, upon the urethra, clothed by the superior fascial layer of the diaphragm. Between the urethra and the vagina only a slight interval exists, through which a few fibers of the sphincter interdigitate with those from the opposite side of the perineum. The bulk of the muscle fibers of the so called sphincter of the urethra actually terminates in the wall of the vagina, as does the musculature of the levator ani. The space between the vagina and the rectum is again so narrow that fibers can scarcely be traced across the midline at that point. The most posteriorly placed muscle fibers of the urogenital diaphragm do not terminate as muscle fascicles in the wall of the rectum, rather it would seem that there are aponeurotic extensions to the rectum of those muscle fibers

²That part of the urethral sphincter muscle which ends in the vagina is 1.3 centimeters wide, that which terminates in the urethra is exactly half that width. The pelvic urethra, which would correspond to the prostatic portion of the male, is 2.5 centimeters in length. The urethra measures 1.4 centimeters in the transverse direction, 0.8 centimeter in the sagittal. It is apparent from probing its lumen that an appreciable dilatation occurs between the internal meatus and the level of the urogenital diaphragm.

which are contributed to the perineal body. They affect only the anterior third of the rectal wall, the remaining posterior two thirds of the rectum receives fibers only from the pelvic diaphragm.

ISCHIORECTAL FOSSA

Just inferior to the line of attachment of the combined origin of the pubococcygeal portion of the levator ani muscle and superior to the bony origin of the urogenital diaphragm next below, is situated the obturator fascia, as it forms the lateral wall of the anterior recess of the ischiorectal fossa (Fig 3). Medially, near the viscera, this recess is a mere cleft along the line of fusion of the muscles and investing fascias of the urogenital and pelvic diaphragms. Its roof is the pubococcygeal portion of the levator ani (retracted in Fig 3 to reveal the posterior recess of the same fossa). Its floor is the gluteus maximus muscle. Crossing this space are the vessels which will be described hereinafter. At the medial limit of the fossa is the external sphincter muscle of the anus.¹

At the anterior limit of both diaphragms their layers virtually meet, the cleft between the levator ani and the subjacent superior fascia of the urogenital diaphragm being a very slight one.² It will be recalled that at this anterior point the urogenital diaphragm

is elevated locally to form bands which we have chosen to name the "pubo urethral ligaments."

BLOOD VESSELS

Arteries From the internal pudendal artery two vessels are given off, the posterior one to structures in the anal triangle, the anterior to those in the urogenital (Fig 3). The posterior stem is the inferior hemorrhoidal artery which sends branches to the anal canal and, enroute several to the fatty tissue in the fossa. The anterior stem divides into two branches, from the hinder one of the two, twigs are given off to the musculature in the two compartments, one twig, the perineal artery, pierces the base of the superficial compartment. The forward branch, like the others, courses anteriorly, remaining near the lateral wall of the anterior recess in the substance of the urogenital diaphragm, therein it gives off muscular branches and sends twigs to the vagina.³ The main stem continues forward as the clitoral artery. **Veins** The veins in general follow, in plexiform manner, the arterial stems.

¹The vertical depth of the external anal sphincter is 2.3 centimeters. While anteriorly the two diaphragms, pelvic and urogenital, are in contact posteriorly—at the hind limit of the ischio-rectal fossa—the two are separated by a distance of 4.0 centimeters, the distance of the lateral wall of the ischio-rectal fossa, this corresponds to the posterior limit of the pubococcygeal muscle. Laterally, the distance of 7.0 centimeters intervenes between the line of origin of the muscle and the inferior margin of the rectal tuberosity. The urogenital diaphragm is 3.0 centimeters in length (measured in parasagittal plane) and is situated to the rectum. The urethra, vein and duct from the obturator fascia to the line of the diaphragm is 5 centimeters measured at the anterior margin of the urethra. At the posterior margin of the urethra the corresponding urethra is 2.2 centimeters (this line passes through the cleft between the urethra and vagina). At its posterior margin the diaphragm is 4.0 centimeters wide (this line passes between the rectum and vagina). The thickness of the diaphragm posteriorly is 3 to 4.0 millimeters (the thickness of the anterior portion of the pelvic diaphragm is 2.5 millimeters, superiorly with the thickness of the posterior margin of the coccygeus is 5 millimeters).

EARLY SURGERY IN BILIARY DISEASE

E L ELIASON, B A , M D , Sc D , F A C S , and J PAUL NORTH, A B , M.D , F.A C S ,
Philadelphia, Pennsylvania

STATISTICS from the large medical clinics in this country show that biliary disease is the most frequent single cause of indigestion, and that 60 per cent of the complaints made to the physician are referred to the gastro-intestinal tract. Expressed differently it can be safely stated that 15 per cent of the population of the United States suffers from biliary disease. This figure increases to 30 per cent after the age of 45 years. In the past the diagnosis was made entirely upon clinical findings and history and consequently many cases were missed until the extracystic complications of jaundice, pancreatitis, cholangitis, etc., showed the true state of affairs. Today, however, there is but little excuse for overlooking biliary disease. Eighty per cent of our own diagnostic failures have been due to inability, through linguistic difficulties, to obtain a satisfactory history. We never operate on dye evidence alone. The use of the x-ray, the dye test, biliary drainage and a careful history should, and has, resulted in earlier and more frequent diagnosis and also in establishing in people's minds the fact that indigestion, gas, dyspepsia, eructations, etc., are merely symptoms of a disease that requires surgery to establish a cure. And yet vital statistics of the insurance companies show that the nation's mortality from this condition is just as high as it was 24 years ago, despite early and better diagnosis and we hope better surgery with vastly improved pre-operative and postoperative care. There is but one answer—and that is delay in the proper surgical treatment while unjustified medical treatment is continued. Medical treatment is rarely, if ever, justified for symptoms producing calculi with or without complications. It is to be remembered that silent gall stones do exist. These rarely if ever require protective surgery but all others do require both protective and corrective surgery. The patient, the physician, and even the surgeon have been all too prone in the past to

procrastinate. Surgery practised early in the disease and early in the acute attack has produced a remarkable reduction in morbidity and mortality.

ACUTE CHOLECYSTITIS

At the moment the management of acute cholecystitis is the most controversial topic in connection with the surgery of the gall bladder. Surgeons of outstanding ability are divided in their opinion as to whether it is best to operate on these cases immediately or after the acute attack has subsided. The arguments for immediate operation are that the complications of empyema, gangrene, and perforation occur in acute cholecystitis as they do in acute appendicitis, that these complications frequently are not recognized since the severity of the clinical symptoms does not run parallel to the pathological changes in the gall bladder, that the mortality due to these complications offsets any reduction in mortality which may accrue from delaying the operation, and finally that the patient is spared needless pain. The arguments for delay are that the analogy between acute cholecystitis and acute appendicitis is not valid in that gangrene and perforation are not as likely to occur in the gall bladder as in the appendix, that even if perforation does take place there is a far greater probability of the resulting peritonitis being localized by adhesions, that the gravity of any operation on the gall bladder requires that the general condition of the patient be as favorable as possible, and that the edema of the gall bladder wall during the acute phase makes operation unduly hazardous. In the surgical literature of the past few years the voices of those who favor immediate operation have been raised more loudly than those holding to a conservative viewpoint. This has upset completely the formerly accepted opinion that operation should be withheld until the acute process "cools off." Miller, after having two

patients die from perforation during the period of expectancy, reviewed a series of 200 cases from the Massachusetts General Hospital and observed that in the fatal cases the period from the onset of acute symptoms to operation averaged 15 days, while in those who recovered it was 8.3 days. Zininger noted that of the patients whose operation was delayed only 37 per cent improved, 35 per cent showed no significant change, and 27 per cent became definitely worse. Stone contends that the tendency to perforation and spreading peritonitis from acute cholecystitis differs only in degree and not in principle from the course of acute appendicitis or perforating ulcer and that the patients who are going to become worse with delay require prompt operation, while those in whom the symptoms would subside do just as well with early surgery. Judd and Phillips noted an incidence of the complications of gangrene and perforation in 13.4 per cent of cases of acute cholecystitis. They subscribe to the plan of early operation with reservations, believing that in certain cases it is wiser to postpone the operation for a long time and that there can be no set plan for dealing with this disease.

Smith, influenced by his experience at St. Luke's Hospital in New York, feels that immediate operation should not be done without urgent indication and, particularly in the older patients and the poor risks, if the course is favorable under observation, it is wiser to wait for 'cooling off'. Heuer is emphatic about the desirability of early operation, pointing out in a review of cases from the New York Hospital that the incidence of extracholecystic abscess in acute cholecystitis is 10.5 per cent as compared with a 17.5 per cent incidence of perforation in acute appendicitis. In Heuer's series, all of whom were operated upon promptly, the operative mortality was only 2.1 per cent unless perforation had occurred prior to operation in which case it was 12.5 per cent. Taylor places the operative mortality at 5 per cent if operation is done during the first 4 days of the attack and at 24 per cent thereafter but adds that no case is so urgent that pre-operative administration of adequate amounts of glucose can be neglected.

Confusion has arisen due to the failure of many advocates of early surgery to state clearly

- 1 Whether immediate operation means an emergency procedure done within an hour or two of the onset of the illness or after the patient's admission to the hospital, or one done after complete studies can be made to assess the patient's condition and the time allowed for the required pre-operative preparations to be carried out,

- 2 Whether cholecystectomy is done as a routine procedure or the operation adapted to the findings,

- 3 Whether the incidence of the late complications of biliary fistula and strictures of the ducts following the removal of acutely inflamed edematous gall bladders has increased therefrom.

Preliminary treatment. In cases with a positive or proved diagnosis seen during the first few hours of an attack, morphia hypodermically should be given at once and everything withheld by mouth. Fluids, preferably glucose 5 per cent in salt solution, is given by venoclysis. Operation is undertaken as soon as the necessary general medical survey can be carried out, the frequent co-existence of diabetes and myocarditis with biliary disease being kept in mind. At this stage the absence of edema permits the ideal cholecystectomy to be performed as a rule. Those patients who have been ill 24 to 36 hours without adequate treatment are also best managed by morphia, venoclysis, and starvation for 12 to 18 hours. If after this period any one symptom fails to subside, operation is done. Similarly patients admitted after 24 or more hours, who are still ill despite proper treatment, i.e., morphia and the withholding of everything by mouth, should have prompt operation. It has been our experience that in patients who have had acute obstructive gall bladder disease for 4 or more days the symptoms will not as a rule subside completely under any treatment except surgery; hence further delay is dangerous and useless. In all three groups the procedure may be either cholecystostomy or cholecystectomy depending upon the local conditions which govern safe surgery such as induration or edema around the ducts obscuring the

anatomy, pancreatitis, jaundice, perforation, etc

When this expectant mode of treatment is adopted and the patient's course is favorable, operation may be deferred until the temperature has been normal at least a week, and the local tenderness has entirely disappeared. Flint points out that usually some pericholecystitis accompanies acute inflammation of the gall bladder and that operation done too soon may result in the spreading of this infection. Furthermore the surgeon is frequently surprised at the amount of residual edema and lymphatic adenopathy found in cases which have apparently subsided. This increases the technical difficulties of the operation and also the hazard of injuring one of the ducts. The pathological state of the gall bladder cannot be safely estimated by any physical or laboratory tests—hence the danger of delay. Not infrequently the problem will arise of persuading a patient to have the operation when he or she seems to have recovered. Such patients are courting certain trouble, and the necessity for operation should be insisted upon.

In determining upon the operation to be done, the crux of this problem lies in the recognition not only of the fact that acute cholecystitis demands early surgical intervention but that the operation must be suited to the conditions of acute local infection. Accordingly the procedure which may be ideal from the standpoint of ultimate morbidity may have to be modified for the sake of immediate mortality. Cholecystectomy is a better operation than cholecystostomy but the latter may frequently be safer and more prudent in the presence of acute inflammation. The rule must be observed absolutely that cholecystectomy should never be done unless the relationships of the hepatic, cystic, and common duct and the cystic artery can be clearly visualized by the surgeon. Granting that in all cases cholecystectomy is more satisfactory from the standpoint of ultimate results, the indications for cholecystostomy may be stated as follows. (1) when the condition of the local tissues militates against safe removal of the gall bladder, (2) when the physical difficulties of obesity, uneven anesthesia, poor illumination or inadequate assistance make proper ex-

posure impossible; (3) when serious local complications, such as jaundice, pancreatitis, or carcinoma call for drainage only, (4) when age or serious renal cardiovascular or pulmonary complications indicate that surgical intervention should be simple and expeditious. The safety of the patient is greatly enhanced if the surgeon will recognize not only his own but the limitations of his patient, and stops with a cholecystostomy rather than attempting too much at one operation.

CHRONIC CHOLECYSTITIS

Surgical treatment is indicated in most cases of chronic cholecystitis with or without stones provided the diagnosis is reached after careful investigation which excludes other possible sources of pain or indigestion. The laboratory findings must not be overemphasized in making this diagnosis unless they are in agreement with the clinical history. The roentgenologic demonstration of gall stones does not necessarily imply that these are responsible for the patient's symptoms, since silent stones are frequently carried for many years. It is for this reason that every effort must be made to exclude extrabiliary causes before subjecting the patient to surgery for failure to do so may result in disappointment to both patient and surgeon. Medical treatment is justifiable so long as it gives uninterrupted relief. There is a tendency in this as in other diseases of a chronic and not completely incapacitating nature to procrastinate before submitting to a major surgical procedure. It must be remembered that not only do the risks and the technical difficulties of biliary surgery increase with delay but after the infection has extended to adjacent organs removal of the gall bladder cannot be expected to cure the patient. Graham aptly illustrates the peril of procrastination by citing operative mortality figures for cholecystectomy. If done after two attacks it is 2 to 3 per cent, after three or more attacks, 8 to 9 per cent, in the presence of jaundice, 10 to 12 per cent, and with pancreatitis it is 50 per cent. Mason estimates that about one third of his patients are relieved by a medical regimen; the others either submit to operation after a few years or should do so but refuse.

The results of surgery in cholelithiasis are better than in non calculous cholecystitis. This may be due in part at least to the greater accuracy of diagnosis when history of typical colic is elicited. Cholecystectomy likewise gives better results than cholecystostomy. The former is the operation of choice provided the surgeon is able to visualize clearly the relationships of the cystic, hepatic, and common ducts and the cystic artery and provided the condition of the patient warrants the performance of the more extensive operation. There are instances in aged or poor risk individuals when simple removal of stones and drainage of the gall bladder is wiser than cholecystectomy.

Electrocardiographic studies are desirable but myocardial disease should not contraindicate gall bladder surgery. There is increasing evidence that removal of the gall bladder may improve the cardiac condition, particularly in patients with arrhythmias. Provided these cardiac patients are compensating or can be restored to compensation by bed rest and digitalis, they present no more serious surgical risk than do those with normal hearts.

Infection of the bile by the bacilli of typhoid fever is an indication for cholecystectomy. These typhoid carriers present a public health menace through the periodic discharge of organisms into the intestinal tract. This source of infection can be eradicated only by removal of the gall bladder. Coller and Forsbeck report 88 per cent of cures in a series of 16 typhoid carriers operated upon and recommend that carriers who are under the age of 50 be subjected to cholecystectomy whether or not they show clinical evidence of cholecystitis. In the older patients the risk of operation is greater and discretion must be used by advising operation only when the usual indications exist.

Operative technique—Cholecystostomy. Infiltration anesthesia with procaine may be used in bad risk patients in which the simplest form of operation is to be done. Whenever circumstances permit, spinal or inhalation anesthesia is preferable since it gives more adequate exposure and enables the surgeon to do a more satisfactory operation.

The incision may be through the upper right rectus, an approach which is far from ideal anatomically but gives good exposure or it may be an oblique subcostal one in which the muscles are split in the direction of their fibers at the outer border of the rectus and sufficient of the rectus fibers divided transversely to give access to the gall bladder. The latter spares more of the nerves supplying the rectus abdominis and thereby diminishes the danger of subsequent incisional hernia. The paramedian incision is preferred by some but in males at least the gall bladder is apt to be so far laterally as to be reached with difficulty by an approach which is so near the midline. The placing of the drain presents difficulties in this incision also although it may be brought out through a lateral stab wound.

Our preference is for the subcostal approach, the line of skin incision being one finger breadth below the costal margin and parallel with it. When the muscles are split, a finger is inserted into the peritoneal cavity and then several sutures are taken through both sheaths of the rectus down to the subperitoneal layer. These sutures prevent retraction of the muscle within the cut edges of its sheath and facilitate closure without a dead space. The incision may be extended across the midline if desired by opening the falciform ligament. Upon opening the abdomen in every case, but especially when dealing with acute inflammation, the surgeon should carefully isolate the gall bladder by gauze packs before it is opened. When the organ is tensely distended, aspiration with a syringe and hollow needle will facilitate the necessary manipulations. The gall bladder is then grasped with Allis clamps and opened at the fundus. An aspirating device with a large blunt tip should be at hand. Stones may be removed with the aid of a scoop or frequently they can be grasped with a curved hemostat. Stones impacted in the ampulla or in the cystic duct are often difficult to dislodge. However, the whole object of the operation is missed unless all stones are removed. The senior author and L. K. Ferguson have devised a cholecystoscope which is on the order of a short sigmoidoscope and carries a light at the tip. This is a great aid in visualizing the inaccessible portions of the gall bladder. When all

tones have been removed, clear bile may enter the gall bladder although often the edema about the cystic duct prevents its immediate appearance. A catgut suture should be placed through the edges of the gall-bladder wall transfixing a rubber tube. Then when a purse-string suture is placed and drawn taut, pushing of the tube downward into the gall bladder will help to invert the edges of its wall around the tube. Usually a second purse-string suture will be required to ensure a snug fit around the tube. If there is gross contamination, a soft cigarette drain should be placed alongside of the gall bladder before the wound is closed. As the skin sutures are placed and before the dressings are applied, the cholecystostomy tube should be securely anchored to the abdominal skin by two long narrow strips of adhesive tape, which in turn pass through a safety pin attached to the tube by means of a silk ligature surrounding it. We have had trouble with tubes being pulled out prematurely because they were not securely fastened in place, or because the adhesive anchorage was not renewed every 4 or 5 days. The tube should be promptly connected with a drainage bottle slung at the side of the bed and a record kept of the amount of material which drains into it. This should be included on the output side in the daily calculation of fluid balance. The usual cholecystostomy tube remains in place for from 10 to 14 days although in certain instances prolonged drainage may be desirable. Cholecystostomy, although a stop gap procedure in many instances, has resulted in cures in approximately 65 per cent of the patients upon whom we have employed it. It is our impression, although not checked, that the wounds in these cases compare favorably with the cholecystectomies as far as herniation occurrence.

Cholecystectomy. From the technical standpoint considerable muscular relaxation is essential for proper exposure. Nitrous oxide and oxygen alone will not provide this in most cases even with an expert anesthetist. Cyclopropane or ethylene may do so. Ether by open drop or in combination with other gaseous agents is the most dependable of the inhalation methods. Due to the characteristic short necked, wide chested configuration

of many patients with gall-bladder disease, the endotracheal technique of administration of inhalation agents is often of great aid in insuring an unobstructed airway and controlling the depth of anesthesia. Local infiltration with novocain has been espoused by some enthusiasts but requires considerable skill and much patience. Splanchnic block has never been in great favor in this country and possesses no great advantages over spinal anesthesia. The latter is highly satisfactory for upper abdominal surgery although it must be employed with discretion due to its inherent dangers. The choice among the various suitable methods of anesthesia must be made with due regard to the particular requirements of the individual patient.

Subcostal oblique or right upper rectus incisions, as described for cholecystostomy, are used.

Operative technique. The operation should begin with an exploration which includes not only the biliary system but the stomach, duodenum, pancreas, appendix, and colon. The surgeon then knows how much must be done and is not embarrassed by the tardy discovery of unsuspected lesions at a time when the patient has had all the surgery that he can stand. The intestines are packed off and exposure obtained by the use of two or at most three retractors. One retracts the duodenum downward, the second draws the falciform ligament toward the left and the third may be required to elevate the lower surface of the liver. There is more than one way of removing a gall bladder, but we prefer first to identify the cystic duct and its relation to the hepatic and common ducts, ligate it, and the cystic artery and then proceed with the dissection of the gall bladder from its bed, beginning at the ampulla. This enables the operator to visualize clearly these structures by reason of the dry field and permits the accomplishment of the difficult and precarious portion of the operation with the best visibility. Beaver has pointed out that the textbook description of the relations of the biliary ducts obtains in only 58 per cent of the cases. In 26 per cent the hepatic and cystic duct run parallel to one another and the former may be injured if care is not exercised. Accessory ducts are present

in 87 per cent, the most common anomaly being an accessory right hepatic duct arising from the cystic. Ligation of this may be fatal and leaving it open will result in biliary fistula. The first step in removal is to elevate the gall bladder by placing a clamp on its ampulla, then to split the peritoneal coat over the ampulla of the gall bladder and expose the ducts. Gauze dissection will aid in exposing the cystic duct although hemorrhage may be encountered from the small veins lying anterior to it. It is helpful to remember that the veins in the plexus over the cystic duct lie parallel with it whereas over the common duct they form a network. If exposure is inadequate at this point, it is sometimes helpful to aid in the rotation of the liver by placing a gauze pack over its dome. Using a ligature carrier or a curved hemostat, two strands of No. 1 chromic catgut are passed around the duct and the latter is doubly ligated close to its juncture with the common hepatic duct. A clamp is then placed on the duct between the bladder and the ligatures to prevent spilling of bile and the duct is divided. The stump may be cauterized with phenol and the ligature nearest the common duct cut short. The other ligature should be left long as a guide until the surgeon is ready to close the wound. The cystic artery can usually be palpated even though not seen at this point and should be brought into view and ligated close to the gall bladder since it sometimes has a branch running to the right lobe of the liver. The remainder of the operation is usually not difficult unless the gall bladder is deeply buried in the liver. As the serosal reflections are divided the gall bladder comes away from its bed. Hemorrhage is controlled by placing a few interrupted sutures of No. 0 catgut through the cut edges of the peritoneal coat. An infected gall bladder bed should not be closely sutured. Venous ooze from the under surface of the liver can often be checked if a small bit of muscle is cut from the edge of the incision and placed against the liver surface making gentle pressure against it for several minutes. The gall bladder should not be completely severed from the liver until all bleeding is under control since as soon as this is done the liver retracts upward under the costal

margin. We routinely place a soft cigarette drain in the fossa above the duodenum bringing it out on the lateral angle of the wound. We have never had cause to regret this procedure. Not infrequently bile stained drainage material for several days makes the surgeon thankful that the wound was not tightly closed. Advocates of non drainage appear on the horizon now and then only to meet catastrophes sooner or later that make them return to the use of drainage. Moynihan once said that "as I grow older a wee bit of a drain in these cases makes me sleep better." The wound is closed in layers, a continuous row of No. 1 chromic catgut sutures being used for the peritoneum and interrupted sutures of fine alloy steel in the aponeurosis of the muscles. The skin is closed with the same steel alloy. The drain may be removed on the second or third day if the progress is entirely satisfactory. Cholecystectomy performed for gall bladder disease uncomplicated by common duct disease, pancreatitis, etc., has given us 94 per cent cures.

COMMON DUCT OBSTRUCTION

Obstruction of the common duct whether from calculus, stricture, neoplasm of the duct itself, or the compression of an extrinsic mass will produce the characteristic manifestation of jaundice. Since the most common cause, common duct stone, is amenable to surgical relief, and the other causes may be relieved if not cured, most patients with common duct obstruction should be given the benefit of operative exploration. Hemolytic icterus and intrahepatic biliary obstruction should be excluded by laboratory tests of which the Van den Bergh bromsulphthalein and blood fragility tests are the most significant. Estimation of the degree of jaundice is of importance and whereas the hue of the skin and the color of the stools serve as a rough guide, a determination of the icteric index is more accurate. When the obstruction is due to a progressive lesion such as stricture or neoplasm, the jaundice also is progressive and relentless. With common duct stone there are usually periods during which some bile flows into the duodenum and the jaundice accordingly lessens intermittently. Patients with common duct

obstruction present serious risks for surgery because there is coincident liver damage and also because of the hemorrhagic tendencies inherent to jaundice. The time for operation must be chosen with discretion. As a general rule it is inadvisable to operate while the jaundice is increasing unless it is obvious that a desperate chance must be taken. On the other hand, when the jaundice is clearing, it is well to wait for the maximum improvement. If the level of jaundice reaches a peak and levels off, nothing is gained by further delay.

Prior to operation the ordinary fluid and nutritional requirements must be met and special measures must be instituted. We know that the livers of jaundiced patients are deficient in glycogen and infiltrated with fat. The administration of glucose is imperative because it serves as a source of energy which can be easily metabolized and this obviates further depletion of liver glycogen. In addition to its value from the metabolic standpoint, glucose exerts a favorable effect upon blood coagulation reducing the tendency to hemorrhage. Many patients are able to take sufficient quantities by mouth in the form of sweet fruit juices or hard candy. The oral route should always be used when available; otherwise glucose may be given intravenously. The other important anticoagulant measure is the transfusion of blood. Small amounts (100 c cm) given repeatedly are of great value. In the presence of anemia larger transfusions should be employed since reduction in red corpuscles greatly increases the operative risk. Calcium has had a vogue as an anticoagulant although there never has been adduced definite evidence that reduction in serum calcium is associated with delayed blood coagulation or that clotting is favorably influenced by the administration of the calcium salts. We place no reliance upon it.

The anesthetic agent and the method used must avoid damage to liver cells or disturbance in the blood sugar level. At the same time it must provide sufficient muscular relaxation for adequate deep exposure. Aside from the necrotizing effect on liver cells of such an agent as chloroform, the damage to the liver from an anesthetic is that of the associated anoxemia. Nitrous oxide, avertin,

or the barbiturates are poorly suited since to maintain surgical anesthesia the concentration of oxygen in the respiratory exchange is reduced to a dangerously low level. More potent anesthetic gases, such as ethylene or cyclopropane, permit the addition of larger proportions of oxygen and are more desirable from this standpoint at least. Ether is accompanied by some reduction in oxygen capacity and content and has a disturbing effect upon blood sugar. Nevertheless its obvious advantages are recognized and it may be used with impunity in cases of early or mild disease of the liver. Local infiltration with novocain usually fails to provide the exposure required by the surgeon. Spinal anesthesia obviates this defect and also the undesirable toxic effects. There may be contraindications to the use of spinal anesthesia from the standpoint of the cardiovascular mechanism and in such cases resort may well be to ethylene or cyclopropane provided the skilled anesthetist required for their use is available.

Operations The problems of preparation for operation, choice of anesthesia and post-operative care, are common to all cases of surgical jaundice regardless of its cause. The operative procedure will vary, depending upon the cause of the obstruction of the duct. At this point certain general principles concerned with obstruction of the common duct by stone will be dealt with. In the presence of strictures of the ducts or of malignancy the procedure is covered in the discussion of these subjects.

It frequently happens that the diagnosis of an obstruction of the common duct is not obvious before operation and at the moment jaundice is absent. In such cases, the surgeon must have certain criteria for opening and exploring the duct. The favorable statistics from large clinics to the contrary, there is no doubt that in average hands the morbidity and mortality will be increased by this procedure over that which will follow surgery confined to the gall bladder. Exploration of the duct should not be done as a routine but it ought not to be omitted (1) when there is a history of jaundice, hepatic fever, acholic stools, etc., (2) when a stone can be palpated in the duct even though there has been no jaundice;

in 87 per cent, the most common anomaly being an accessory right hepatic duct arising from the cystic. Ligation of this may be fatal and leaving it open will result in biliary fistula. The first step in removal is to elevate the gall bladder by placing a clamp on its ampulla, then to split the peritoneal coat over the ampulla of the gall bladder and expose the ducts. Gauze dissection will aid in exposing the cystic duct although hemorrhage may be encountered from the small veins lying anterior to it. It is helpful to remember that the veins in the plexus over the cystic duct lie parallel with it whereas over the common duct they form a network. If exposure is inadequate at this point, it is sometimes helpful to aid in the rotation of the liver by placing a gauze pack over its dome. Using a ligature carrier or a curved hemostat, two strands of No. 1 chromic catgut are passed around the duct and the latter is doubly ligated close to its juncture with the common hepatic duct. A clamp is then placed on the duct between the bladder and the ligatures to prevent spilling of bile and the duct is divided. The stump may be cauterized with phenol and the ligature nearest the common duct cut short. The other ligature should be left long as a guide until the surgeon is ready to close the wound. The cystic artery can usually be palpated even though not seen at this point and should be brought into view and ligated close to the gall bladder, since it sometimes has a branch running to the right lobe of the liver. The remainder of the operation is usually not difficult unless the gall bladder is deeply buried in the liver. As the serosal reflections are divided the gall bladder comes away from its bed. Hemorrhage is controlled by placing a few interrupted sutures of No. 0 catgut through the cut edges of the peritoneal coat. An infected gall bladder bed should not be closely sutured. Venous ooze from the under surface of the liver can often be checked if a small bit of muscle is cut from the edge of the incision and placed against the liver surface making gentle pressure against it for several minutes. The gall bladder should not be completely severed from the liver until all bleeding is under control since as soon as this is done the liver retracts upward under the costal

margin. We routinely place a soft cigarette drain in the fossa above the duodenum bringing it out on the lateral angle of the wound. We have never had cause to regret this procedure. Not infrequently bile stained drainage material for several days makes the surgeon thankful that the wound was not tightly closed. Advocates of non drainage appear on the horizon now and then only to meet catastrophes sooner or later that make them return to the use of drainage. Moynihan once said that "as I grow older a wee bit of a drain in these cases makes me sleep better." The wound is closed in layers, a continuous row of No. 1 chromic catgut sutures being used for the peritoneum and interrupted sutures of fine alloy steel in the aponeurosis of the muscles. The skin is closed with the same steel alloy. The drain may be removed on the second or third day if the progress is entirely satisfactory. Cholecystectomy performed for gall bladder disease uncomplicated by common duct disease, pancreatitis, etc., has given us 94 per cent cures.

COMMON DUCT OBSTRUCTION

Obstruction of the common duct whether from calculus, stricture, neoplasm of the duct itself, or the compression of an extrinsic mass will produce the characteristic manifestation of jaundice. Since the most common cause, common duct stone, is amenable to surgical relief and the other causes may be relieved if not cured, most patients with common duct obstruction should be given the benefit of operative exploration. Hemolytic icterus and intrahepatic biliary obstruction should be excluded by laboratory tests of which the Van den Bergh bromsulphthalein and blood fragility tests are the most significant. Estimation of the degree of jaundice is of importance and, whereas the hue of the skin and the color of the stool serve as a rough guide, a determination of the icteric index is more accurate. When the obstruction is due to a progressive lesion such as stricture or neoplasm, the jaundice also is progressive and relentless. With common duct stone there are usually periods during which some bile flows into the duodenum and the jaundice accordingly lessens intermittently. Patients with common duct

woven silk ones are much better. During the irrigation care must be taken not to wash material upward into the hepatic ducts. This may be prevented by plugging the latter with a small piece of narrow gauze packing. After the lower portion of the duct has been washed clean and the catheter passes freely past the sphincter of Oddi into the duodenum as evidenced by the fact that none of the irrigating fluid returns, the procedure should be reversed and the hepatic ducts irrigated in turn.

Before removal of the catheter passing into the duodenum, the operator standing on the patient's left should palpate with his left thumb and forefinger along the duct as outlined by the catheter. This palpable guide will facilitate the disclosure of a stone oftentimes that has up to this stage been overlooked.

Frequently after one is sure that all stones are removed the catheter cannot be passed into the duodenum. This obstruction may be due to the fact that the catheter tip is unable to find the sphincter opening because of its eccentric position with relation to the dilated portion of the duct above it. When this is the case, if the woven catheter is bent about $\frac{3}{4}$ of an inch from its tip so as to form an angle of 15 to 20 degrees to the rest of the catheter, and then inserted and rotated on the long axis while gently pushing upon it, the sweeping tip will often find the eccentric sphincter.

The author routinely drains the common duct with a rubber T-tube. Some surgeons use plain or mushroom catheters. The former slip out too easily and the latter may be difficult to remove. If certain precautions are observed with the T-tube, it will prove very satisfactory. It must not be of soft collapsible material nor on the other hand should it be so stiff as to traumatize the duct. The side arms should be about $\frac{3}{4}$ inch in length and the ends bevelled on their anterior aspects. A notch cut in the cross arm opposite the upright portion allows the side arms to fold and slip out readily when the time comes to remove the T-tube. Interrupted sutures of fine catgut are placed in the wall of the duct above and below the emerging tube to give a snug watertight joint but care must be taken not to narrow the duct in approximating the cut edges. In most cases a cigarette drain should be placed

in the fossa above the duodenum as a precaution before closure of the wound.

Stones impacted in the duodenal portion of the common duct are particularly difficult to dislodge. In some cases it may be necessary to mobilize the duodenum by freeing its superior and lateral attachments and then rotating it forward to expose the posterior wall through which the lowermost portion of the common duct passes. Occasionally a stone in this position can only be removed by a transduodenal approach to the sphincter of Oddi.

Postoperative care After operation these patients have the same need of glucose and blood as before. In addition there are certain problems introduced by the diversion of bile through a choledochostomy tube. The flow must be unimpeded and the tube may have to be gently irrigated with warm saline solution. Too rapid decompression of the biliary system may have untoward effects. The same care must be exercised in this respect as is needed following thoracotomy for empyema or the evacuation of a long standing distention of the urinary bladder. The bile should flow out of the drainage tube intermittently or the tube connected with a decompression apparatus so that the drainage occurs slowly against the pressure of a column of water or gravity. Moreover, the complete diversion of the patient's bile may result in profound biochemical disturbances through the loss of bile salts and other electrolytes. Patients whose bile and pancreatic ferments are being lost in this way sometimes develop marked listlessness, low blood pressure, nausea and debility, sometimes termed "pancreatic asthenia." The deficit can be corrected either by clamping the choledochostomy tube for a long time if this be feasible or perhaps better by returning the bile to the gastro-intestinal tract by pouring it down a duodenal tube which has been introduced into the stomach. As an alternative the bile may be collected, lyophilized (concentrated) and given to the patient in convenient capsules (Mudd). The patient's own bile or that of another patient serves far better as a corrective under these circumstances than does any synthetic chemical substance or ox bile. The length of time a tube is left in the common duct depends upon the circumstances

(3) when the common duct is dilated, thickened or has lost its normal bluish color and appears white or grayish. Unless these rules are followed, stones will be overlooked, and secondary operation may be required.

Eliaeson and Erb recently reported that they had explored the common duct in 18 per cent of a large series of biliary operations with the discovery of stones in the duct in 10 per cent of the total number of cases. When the duct is opened a drainage tube should always be introduced as suture of the duct can not be relied upon.

As a general rule the gall bladder should be removed at the same time that the duct is explored, since it represents a focus of infection even though the disease has extended beyond it. In certain instances however, it is the part of wisdom to do a cholecystostomy and leave the gall bladder in place. Such occasions arise when the nature of the obstructing lesion is such that it may progress after operation or when the surgeon is uncertain whether he has completely and effectively removed the cause of the obstruction.

In the event of a secondary operation the preservation of the gall bladder serves as a useful anatomic landmark in what is apt to be a tedious dissection and also makes it feasible to perform a subsequent short circuiting procedure should it be required. We have made it a rule to save the gall bladder in this way whenever the common duct is large and contains many small stones. The following case illustrates the value of this.

A man 48 years of age was first operated upon in 1931, for recurrent attacks of epigastric pain and jaundice. Stones were found in the gall bladder, the common and hepatic ducts and cholecystostomy and choledochostomy were done. During the ensuing 6 years five additional operations have been performed on this patient usually because of recurrences of pain and jaundice. No further stones have been encountered in the gall bladder but in each instance except the last a large number of soft stones have been found in both the hepatic ducts and in the common duct. The last operation was done for persistent biliary fistula. The gall bladder has not been removed in this patient because it has not contained stones since the first operation. The evidence indicates that this patient's calculi have originated in the liver or hepatic ducts. At each operation the author has been thankful for the presence of the gall bladder as a guide leading to the common duct.

Choledochostomy. Anesthesia requirements in the jaundiced patient are important and are covered in the discussion of common duct obstruction. The incision may be the subcostal oblique or the right upper rectus which have been described in connection with cholecystostomy. The common duct is exposed in a manner outlined for cholecystectomy. With the oblique incision, improved exposure of the duct is obtained by extending the incision across the midline. If adhesions are present they must be carefully separated employing the gall bladder and the cystic duct as a guide leading toward the common duct. The latter appears as a faintly bluish structure beneath the peritoneum in the right free margin of the gastrohepatic omentum. It is overlaid by a plexus of small veins which, if dilated, may give troublesome hemorrhage. When doubt arises concerning which of the structures in the gastrohepatic omentum is the common duct, the aspiration of bile with a fine hypodermic needle attached to a syringe will settle the matter. Two sutures of fine (No. 00) catgut are placed in the wall of the duct by means of a small curved intestinal (Ferguson No. 12) needle. The ends of the suture are left long and clamped to serve as tractors. The duct is then incised in the direction of its long axis between the traction sutures. As the bile pours out it is sucked up by an aspirating apparatus with a fine tip or absorbed by a gauze sponge. The opening is enlarged to admit a duct probe or even the finger. The duct is explored toward the duodenum and then upward in an attempt to locate the obstruction. The thumb and forefinger of the surgeon placed behind and in front of the duct will aid in this exploration and may assist in displacing a stone upward. In conducting this exploration the surgeon can sometimes benefit by taking his position on the left side of the patient and inserting his left hand into the wound. Stone, may be exceedingly difficult to dislodge but sometimes may be grasped by a curved hemostat or stone forceps. When numerous small stones or gravel are encountered, they may be washed out. A woven silk catheter (No. 10-12 F.) is passed down the duct to irrigate it with warm normal saline solution. An ordinary soft rubber catheter is apt to kink upon itself and

present, a biliary fistula be allowed to form and the tract of the latter then be dissected out of the abdominal wall and implanted into the stomach or duodenum. Every one of these procedures will tax the skill of the ablest surgeon. A leak in the suture line may jeopardize the entire result. Furthermore the dangers of cholemic hemorrhage common to all jaundiced patients exact a large toll and the mortality rate is high even with the best of technical performances.

BILIARY FISTULA

The continued discharge of bile through an opening in the abdominal wall after operative tube and drains have been removed, should occasion some perturbation on the part of the surgeon in attendance. It is to be expected that some leakage will occur for a few days following the removal of a cholecystostomy or choledochostomy tube but within a short time all of the bile should be passing through the normal channel into the duodenum. Continued drainage should arouse the suspicion of an obstruction of the duct. This may be due to a stone or to a misplaced ligature. Other and more favorable possibilities are that an accessory cystic duct was not observed during cholecystectomy and is discharging bile through the wound or that the ligature has slipped off the stump of the cystic duct. In both these latter cases the normal bile passage-way into the intestinal tract is patent and under such circumstances the biliary fistula may in most cases be expected to close spontaneously. The importance of the factor of obstruction in the persistence of fistula is well illustrated in the case of drainage of the gall bladder without the extraction of an impacted stone in the cystic duct. Here a more or less continuous communication will persist between the gall bladder and the opening in the skin. It will in this instance discharge mucus rather than bile because the latter is prevented by the impacted stone from reaching the gall bladder, but its behavior is quite different from that following cholecystostomy with a patent duct. The decision to operate or to wait for spontaneous closure in a biliary fistula depends therefore upon the demonstration of the presence or absence of obstruction. Jaun-

dice or clay colored stools give a clue but much more exact information concerning the level and nature of an obstruction is obtained by fluoroscopic observation during and immediately after the injection of a radio-opaque substance, such as iodized oil, into the fistula. This gives a clear delineation of the ductal system and should reveal the true situation. If the injected oil passes readily into the duodenum, operative intervention should be deferred for at least a year. The demonstration of a stone in the common duct calls for choledochostomy. Strictures of the duct require appropriate measures. The final recourse is a dissection of the fistulous tract with implantation of it into the stomach or duodenum. This operation is neither as easy nor as successful in practice as it sounds in theory.

CANCER OF THE GALL BLADDER AND EXTRAHEPATIC BILIARY DUCTS

Carcinoma has been estimated to be found in between 1 per cent and 2 per cent of all cases of disease of the gall bladder and its ducts. This incidence, therefore, is less than the mortality of the best elective cholecystectomy and the removal of silent gall stones can not therefore be urged on the ground of their threat of the development of cancer. The diagnosis of cancer confined to the gall bladder is rarely made before operation and later frequently only by histopathological examination. The obvious surgical procedure is a cholecystectomy unless the growth has extended beyond the confines of the gall bladder.

Cancer of the ducts manifests itself by relentless and painless jaundice. Potter has called attention to the fact that it occurs about as frequently as cancer of the head of the pancreas and about 3 of 5 cases are erroneously so diagnosed.

It is well known that surgical attack on carcinoma of the ducts presents much the same problem as stricture with the additional urgency to perform radical extirpation when feasible. A few cases of successful resection of the common duct with implantation of the stump into the duodenum are on record. More often the only possible course open to the surgeon will be a palliative cholecystogastrostomy or cholecystoduodenostomy.

of the case, e.g., the amount of bile passing through the sphincter of Oddi by the normal route and the degree of hepatitis present. Ordinarily 2 weeks is a sufficient period for drainage but occasionally prolonged drainage of several months is desirable. It is of the greatest importance in these patients to observe both clinically and by laboratory tests the progress of the jaundice. The color of every stool passed or the return from each enema should be carefully noted on the patient's record for this gives a reliable index of the flow of bile through the normal channel into the intestinal tract.

STRICTURES OF THE BILIARY DUCT

Although other etiological factors are possible, the majority of strictures are the result of operative trauma. Their correction presents one of the most difficult problems in abdominal surgery and the operative mortality rate is high, therefore, the utmost caution should be exercised to avoid damage to the ducts in doing biliary surgery. Two or three dangerous practices in the performance of cholecystectomy deserve particular attention. When troublesome hemorrhage occurs from the cystic artery a clamp or a ligature carelessly placed may include the right hepatic duct together with the cystic artery. The same error may be made by placing a clamp blindly on the neck of the gall bladder preparatory to dividing the cystic duct. To insure against this the cystic artery should always be distinctly visualized or palpated and ligated close to the gall bladder either before or immediately after ligation of the cystic duct. If the cystic artery be accidentally torn, a clamp should never be placed blindly in a field obscured by blood. A second common error arises in making strong traction upward on the gall bladder so that the junction of the cystic with the common hepatic and common ducts is peaked. Under these circumstances the ligature intended for the cystic duct may encircle the common hepatic or the common ducts either in entirety or in part. The result will be a biliary fistula if the misplaced ligature blows off or, depending upon how much has been included in the ligature, a partial or complete stricture of the common duct. The

possibility of these calamitous sequelae is ample justification for the absolute dictum that cholecystectomy should never be attempted in cases in which the relations of the three ducts can not be visualized.

The surgeon who opens an abdominal cavity for the repair of damage to the biliary ducts invariably faces a trying and tedious session. The omentum and duodenum will usually be found adherent to the under surface of the liver at the former site of the gall bladder. The identification of the common duct itself may be an exasperating and time consuming problem. Having identified the ducts and demonstrated the level and nature of the stricture, several possibilities present themselves for overcoming the obstruction.

An adequate length of duct proximal to the stricture is a prerequisite to any form of anastomosis. The latter must be accomplished without tension on the suture line and to ensure this it is easier to mobilize the duodenum and draw it upward than to make any downward traction upon the duct itself. An ideal procedure would be a resection of the narrowed portion of the duct and an end to end anastomosis. This is feasible only with very short strictures as otherwise tension will ensue. The sutures must be meticulously placed and should be of the finest material and the needle should be small. Care must be taken to avoid inversion of the edges of the duct wall, thus giving rise to a new stenosis. A rubber tube should be used to maintain patency of the duct during the stage of edema following operation. If anastomosis can not be done, the proximal portion may sometimes be implanted into the mobilized duodenum—hepaticoduodenostomy or choledochoduodenostomy. Plastic procedures to overcome narrowing are rarely applicable. One of the Heineke Mikulicz type which is satisfactory in correcting pyloric stenosis will produce linking if attempted on a bile duct. Occasionally a stricture may be split in the axis of the duct and sutured around a tube. The senior author has successfully followed the suggestion of Dr Julian Johnson that parallel relaxation incisions be made in the duct and a tube be placed in the lumen. Lahey has suggested that as a last resort if insufficient proximal duct tissue is

OBSTETRICAL INFLUENCES ON THE WEIGHT CURVE OF THE NEWBORN

W. C. C. COLE, M D , Detroit, Michigan

THE conception that the "normal" newborn infant may be in a state of mild shock is relatively new. If such a conception proves to be correct, it should greatly modify not only our routine care of newborn babies but many obstetrical procedures.

Practically all laymen and most physicians think of labor from the mother's point of view. The baby usually receives scant attention until the process is over. Many procedures have been advanced in recent years to make labor easier for the mother but very few have been suggested to make delivery safer for the child. After all, the function of labor is to produce healthy children. True progress in obstetrics should certainly be as much concerned with insuring the baby's safe passage through the birth canal, as with making labor more endurable for the mother.

A most casual inspection of newborn statistics should be sufficient to convince anyone that this is not an insignificant problem. In hospital practice, about 4 per cent of the newborn babies are either stillborn or die in the first week of life. More than half of these are due to accidents of labor, especially cerebral injury and asphyxia. It is estimated that about seventy thousand recognized cases of cerebral hemorrhage in the newborn occur in the United States each year. A very large proportion of the inmates of public institutions for the mentally or physically handicapped are cases resulting from birth injury. Therefore it seems appropriate that we gather data which may throw additional light upon the factors responsible for these injuries.

Labor in the human is quite a different problem from that in even the largest of the mammals because of the large size of the infant's head and the disproportion between it and the mother's pelvis. It has been suggested that the amount of trauma to the head, which is necessary under even the most ideal

conditions, is sufficient to produce a considerable degree of shock in the infant. Changes in blood pressure, blood volume, and blood flow in newborn babies, similar to those found in patients with surgical shock have been reported. Clinical evidence of this shock is the apathy, refusal of food, and marked loss of body weight almost invariably observed during the first days of life.

The loss of weight has always been called "the physiological weight loss of the newborn." It has been explained by the loss of meconium and urine from the body, by the vomiting of mucus, and by the fact that the baby usually receives little or no food or fluid during the first days of life.

If we examine the growth curve of the ovum from the time of fertilization until birth, we will observe that it is rapid and continuous. Also, if we examine the growth curve of the infant after it has recovered from the effect of birth, it is again rapid and continuous. It does not seem reasonable that such a marked interruption of development, sometimes involving a loss of 10 per cent of the body weight can be a "physiologic" phenomenon. Furthermore, if the various factors usually listed as accounting for this loss of weight are all added together they are sufficient to explain only a part of the weight lost by most babies. Apparently some changes must occur which have not previously been considered.

One of the outstanding features of "shock" is a disturbance in the water metabolism involving the loss of large amounts of water from the body, chiefly through the skin and lungs. The work of Coller¹ on the water metabolism of patients after operation has demonstrated this thoroughly. While similar studies have not been made on newborn infants, the analogy between them and adults after operation seems sufficiently close to

¹COLLER, F. A., and MADDOCK, W. G. J. Am. M. Ass., 1932, 99, 875-880.

CONCLUSIONS

Early surgery in the acute attack as well as in the course of the disease will reduce mortality and morbidity. Judicious choice of the procedure to be employed is necessary. The surgeon should recognize his own as well as his patient's limitations. It might be better to leave a difficult case of impacted stone behind the duodenum until drainage through a cholecystostomy relieves the dangerous jaundice.

Postoperative care is extremely important. It should be directed toward the prevention of hypoventilation and pulmonary complications by posture, deep breathing exercises, change of position, suction drainage of the stomach as a defense against abdominal distention, the prevention of concealed hemorrhage and biliary peritonitis by the use of a drain, the maintenance of liver function by the use of decompression drainage and the administration of blood or glucose and salt intravenously to sustain metabolic and fluid

balance. Only by strict attention to these principles can we hope to reduce the mortality and morbidity of biliary disease.

curve of any given group by means of a tabulating machine. This permitted analysis of data which would be impossible by means of ordinary hand methods and in addition assured absolute accuracy.

The weight curve for the whole group is shown in Chart 1. This and all subsequent curves are expressed in percentage of the birth weight, rather than in ounces, so as to make comparison of groups of different weights on a common basis. The birth weight is taken as 100 per cent. Figures in parenthesis indicate the number of babies. The other figure is the average initial weight. The loss in weight the second day was 3.47 per cent. The maximum loss occurred on the third day and was exactly 5 per cent of the original weight. This represents a loss of almost exactly 6 ounces for the average baby. Only a very slight increase occurred on the fourth day but from then on the gain in weight was rapid and continuous. On the eighth day, the average baby was 1.33 per cent below birth weight. The maximum loss of 5 per cent of the birth weight is considerably less than the figure usually given for similar groups. VonReuss gives from 6 to 10 per cent as the usual loss. This is probably due to the fact that practically all of the babies in the nurseries at the Woman's Hospital are offered fluids of one sort or another during the first days of life. This, however, is a question which we will discuss at another time.

Chart 2 shows the comparative weight curves of the babies of primiparæ and multiparæ. VonReuss states that the children of primiparæ lose more weight and recover more slowly than those of multiparæ due to the later appearance of the mother's milk. In our series, the curves are practically identical except that at the eighth day, the babies of the primiparæ have not regained as much of their weight. If the trauma of labor is a factor in increasing the weight loss of the newborn, it might be expected that it would be greater in the case of primiparæ, but this is obviously not the case. However, as will be subsequently shown, the duration of labor which is usually much longer in the primiparæ, may tend to offset such an effect.

Chart 3 shows the effect of the various types

Chart 3 Effect of operative delivery

of operative delivery on the weight curves of the newborn. It will be noted that all but one group (high forceps) lost less than the average. While the curve is not shown on this chart, obviously babies born by normal delivery lost correspondingly more than the average. There were 32 babies born by breech delivery in which the maximum loss in weight was but 3.47 per cent. This group was over birth weight on the seventh day. There were 20 babies delivered by version and extraction in which the maximum weight loss was 3.92 per cent. They were practically at birth weight on the eighth day. There were 34 babies born by cesarean section in whom the maximum loss was 4.25 per cent. They were 0.50 per cent below weight on the eighth day.

It should be noted that in all three of these groups, trauma to the head is either absent or greatly reduced because it is not the presenting part and does not receive direct pressure as in the case of cephalic presentation. There were 182 cases in which low forceps were applied. The loss in this group is only slightly less than the average but very definitely so when the size of the group is taken into account. Their better recovery by the end of the period is also significant.

There were 28 cases in which high forceps were applied. The weight curve of this group closely corresponds to the average except for

Chart 1: Average weight loss of all cases

Chart 2

assume that similar processes are taking place. If this be true, the weight lost by the newborn is largely due to water lost from the body and should be more or less an index to the degree of shock.

In the observation of a large number of newborns, we have been impressed by the fact that babies of similar size, apparently born under similar conditions, and fed and cared for in like manner vary widely in the amounts of weight which they lose. Some factors obviously must be operative in one case which are not present in the other. If birth shock is a factor in some of these cases conditions during and after labor which might tend to increase the birth trauma should be possible of detection by an inspection of the delivery record.

With this in mind, we have collected a considerable series of cases on which accurate observations of many of the possible factors which might involve the baby including the food and fluid intake, were carefully recorded and tabulated in such a manner as to make comparison of their various weight curves possible.

In this paper we wish to present an analysis of the influence of various obstetrical and neonatal procedures on the weight curves of different groups of infants. The consideration of the food and fluid intake and a correlation

of the two series will be the subject of a later report.

Between November, 1935, and June, 1936, records were made of all the babies born in the Woman's Hospital at Detroit. These included all social groups and were delivered by physicians with a considerable variation of obstetrical training. Accordingly, a very good general cross section was obtained. During this period, about 1,250 babies were born. Only normal children were included in this study. Any baby who was ill or had a recognized abnormality or whose record was not complete was excluded from the series. The babies in this series left the hospital at the usual time in apparently good condition. This left a group of 996 babies which form the basis of this analysis.

The data were tabulated according to the punch card method. All data concerning each child were punched into an individual card according to a previously established code. This included data about the pregnancy, delivery, neonatal period, the weight for each of the first 8 days and a complete record of the food and fluid intake for each day. After the cards were complete it was a simple matter to sort them into any desired group or subgroup by means of a mechanical sorting machine, and to obtain the cumulative weight

Chart 6 Effect of resuscitation

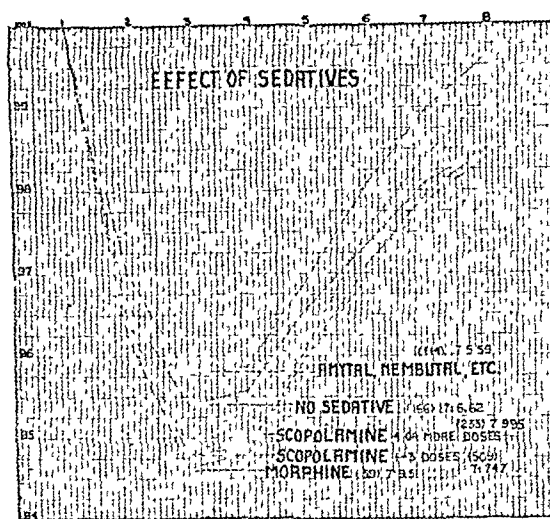

Chart 7 Effect of sedatives

canal tends to minimize the trauma to the head

Chart 5 shows the effect of pituitrin on the weight curve of the infant. There were 24 cases in which pituitrin was used in the first stage of labor and 102 in which it was used during the second stage. The initial weight loss of both groups does not seem to show any significant deviation from the average curve although both groups lost slightly more. In both cases, however, the recovery is slower than average and when pituitrin was used in the first stage, the babies were 2.44 per cent below weight on the eighth day. This is nearly twice as much below weight as the average baby. Whether this bears any relation to the use of pituitrin or is merely an accidental finding is open to question. It would naturally be expected that the pituitrin would increase the trauma to the baby's head, but if so it is not indicated in the amount of the initial loss.

Chart 6 shows the effect of resuscitation in the newborn on the subsequent weight curve. The cases were divided into two groups, those in which the asphyxia was mild, and those in which it was severe. Severe cases were those with prolonged cyanosis, in which the tracheal catheter was used or in which artificial respiration was needed.

The curve of those babies in whom resuscitation was not used, corresponds almost ex-

actly to the average. When mild measures were necessary the loss was slightly less; when severe measures were used it was slightly more. If there is any significance to these findings, it is not clear to the writer.

Chart 7 shows the effect of sedatives given to the mother on the infant's weight curve. These are divided on the following basis, no sedative, scopolamine 1 to 3 doses, scopolamine 4 or more doses, morphine (usually in combination with scopolamine), and amytal, nembutal, etc.

In cases in which patients received no sedative the babies lost considerably less than average (4.59 per cent). Those receiving amytal, etc. lost a maximum of 4.23 per cent, which is strikingly less than average. Recovery in this group was also better than in any other. The amount of scopolamine given did not seem to alter the curves of those two groups nor did the addition of morphine cause any appreciable change. All of these latter groups lost slightly more than average and were somewhat slower in recovery. There are two possible explanations for these findings. Amytal, etc., act quite definitely to slow labor, whereas scopolamine does not. Babies whose mothers receive amytal are usually very listless and apathetic for the first 24 hours. Scopolamine seems to render the baby hypertonic and irritable. The energy conserved in

Chart 4 Effect of duration of labor

Chart 5 Effect of pituitrin

the continued loss of weight into the fourth day. This could perhaps be interpreted as the result of increased trauma but is more probably due to special feeding problems. Mothers in whom high forceps application is necessary would probably be in poor condition longer than the average mother with a consequent reduction in milk production.

It has been suggested that in the case of breech and version deliveries, meconium is often expelled during labor so as to make the original weight less and the percentage loss correspondingly less. However it appears that meconium is only occasionally expelled and then rarely as much as an ounce. If we should recalculate these cases on the basis of one ounce more on their original weight (which does not seem likely) their weight curve then would be very close to the cases delivered by caesarean section.

In any event it seems very striking that in the groups in which trauma to the head is minimized the weight loss of the babies was markedly reduced. There is also room for argument that the use of low forceps, toward the second stage of labor, somewhat reduces the trauma to the baby's head.

Fully as significant as the original loss in evaluating the amount of injury to the baby is the very considerably faster recovery made by all of these groups. These results should not be interpreted as favoring breech and version delivery. These records are only on normal babies. It is well known that the incidence of tentorial tears is much higher in this type of delivery.

Chart 4 shows the effect of the duration of labor upon the weight curve of the baby. The cases were divided into four groups. Those in which the labor was less than 6 hours in which it was from 6 to 12 hours from 12 to 24 hours and over 24 hours. There seems to be little if any difference in the curves of the babies in the first two groups. Both of them lost slightly more than the average and are significantly slower in their recovery by the eighth day. The 12 to 24 hour group conforms almost exactly with the average but the loss is slightly less throughout. However in the group in which labor lasted over 24 hours the difference is extremely striking. The maximum loss was but 3.06 per cent, and they were 1.07 per cent above birth weight on the eighth day. Long slow labors are often the result of weak pains. This marked reduction in the weight loss of this group coupled with their very good recovery strongly suggests that slow gradual progress of the child through the birth

Chart 10

Chart 11

each infant. It would seem that the reason for the variation in the drop in temperature lays not in external influences but to conditions within the babies themselves. It may be that the drop in temperature is in itself responsible for the increased loss in weight but it seems much more likely that the drop in temperature is merely another method of measuring the degree of birth shock. Lowered body temperature is one of the characteristics of shock and it would be natural to find the loss of weight corresponding to the drop in temperature if we assume that both of these factors are indices of shock.

Charts 10 and 11 show the effect of the time of tying the umbilical cord on the babies weight curve. In Chart 10, the cases are divided into two groups according to whether the cord was tied before or after pulsation had stopped. It will be seen that when the cord was tied before pulsation stopped the loss in weight was distinctly greater and that the curve remained below the other group throughout. In Chart 11, the cases were divided into three groups: (1) the cord was tied in less than 1 minute after birth; (2) it was tied between 1 and 3 minutes after birth; and (3) it was not tied until more than 3 minutes after birth. It will be readily seen that the longer the time that elapsed, the less the weight the babies lost. It has been estimated that the baby re-

ceives from 1 to 2 ounces more blood (a very considerable amount to a newborn) when the cord is not tied until after pulsation stops than when it is tied at once. Inasmuch as blood volume is one of the important factors in the

Chart 12

Chart 8 Effect of anesthetic ether

the first group might possibly reduce the weight loss, or the depression of respiration might cause less water to be lost through the lungs. The effect, however, seems very definite. The interpretation will bear further study.

Chart 8 shows the effect of ether administered to the mother on the weight curve of the baby. The cases were divided into those receiving no anesthesia, those receiving ether for less than 15 minutes, those receiving ether from 15 to 60 minutes, and those receiving ether for over 1 hour. It is very evident that the amount of ether administered to the mother bears a direct relationship to the initial weight loss of the infant and to the rate of recovery of the weight. The more ether the mother received, the less the baby lost and the more rapid the recovery. When no anesthetic was given the maximum loss was 5.33 per cent and the babies were still 2.37 per cent below weight on the eighth day. When ether was given for over 1 hour, the maximum loss was 4 per cent and weight at the eighth day was +.58 per cent. There are several possible interpretations of this very interesting observation. It might be that the administration of ether slows down the progress of labor and may have a direct effect on the child's nervous

Chart 9 Effect of drop in temperature

system, or as seems quite likely, it might modify the baby's respiration with consequently reduced water loss from the lungs.

Whatever the explanation, the effect seems so definite as to leave little doubt that ether given to the mother tends to reduce birth shock in the baby.

Chart 9 shows the effect of the drop in the baby's temperature during the first hours after birth. The cases are divided into groups according to the lowest point the temperature reached in the first 24 hours after birth, one group for each degree. It will be observed that with a single exception (those between 95 and 96 degrees) the drop in weight is directly proportional to the drop in temperature. It is possible that in the exceptional group special administration of parenteral fluid may have been used in certain cases which modified the curve of this group. The maximum loss in those in which the temperature fell below 93 degrees was 5.77 per cent while in those where it did not fall below 99 degrees, it was but 3.80 per cent. The regular progression upward of the weight curve with each degree of rise in temperature is very striking and must be significant. The rate of recovery is also proportional to the original loss. The temperature of the delivery room was never below 85 degrees and usually near 90 degrees. Heated cribs are provided for the reception of

EVALUATION OF THE INTRADERMAL TEST FOR PREGNANCY

SUSANNE R. PARSONS, M.D., F.A.C.S., Santa Barbara, California

THE report of Gilfillen and Gregg on a "new, rapid, and economical" test for pregnancy which appeared in September, 1936, has led some of us to attempt to repeat their work. It seems worth while at this time to collect the data presented in the reports of these other workers and to add thereto a small series of tests which I have carried out

An ideal test for pregnancy must meet certain requirements. It must first and foremost be at least 95 per cent accurate. It should be rapid, economical, and so simple that it may be available to workers lacking elaborate laboratory facilities. The Aschheim-Zondek test meets the first but requires several days and a large and always available supply of animals. Its various modifications offer little improvement in these respects.

Gilfillen and Gregg report that the skin test for pregnancy meets all the above requirements and in their hands they found it "proved more delicate than the Aschheim-Zondek test in border cases." The test is based on the idea that an anterior pituitary-like substance is present in the circulation of pregnant women, therefore these women would not be sensitive to this substance injected intradermally. Non-pregnant women would show a reaction, as it would not be present in the blood stream. Their technique consists of the intradermal injection of 2 minims of antuitrin-S in the flexor surface of the forearm, after it has been cleansed with sterile water. The reaction occurs usually within a few minutes, or may be delayed as long as 2 to 3 hours in elderly women. An area of erythema, 7 to 40 millimeters in diameter about the site of injection, develops in non-pregnant patients. In pregnancy no reaction occurs. They used the test not only for pregnancy, but in gynecological conditions, as abortion, ectopic pregnancy, hydatidiform mole, and teratoma of the ovary. A series of

24 controls, known non-pregnant patients, confirmed the accuracy of their test, which they state to be reliable in all these conditions.

Although Gilfillen and Gregg make no mention of the fact, this test was neither new nor original with them. It was first used by Porges and Pollatschek and reported before the Society for Internal Medicine in Vienna, March, 1929. Prolan was used and the readings were made the following day. This report was enthusiastic and it was claimed to be reliable in all cases but one, a woman with a hypophyseal tumor. No statement was made as to the number of cases tested, however.

Alfred Deutsch repeated this work on a series of 45 pregnant and 65 non-pregnant women. He concludes that there is no essential difference in skin reaction between the pregnant and non-pregnant. Only 11 of a series of 65 non-pregnant women gave a strong reaction. Strauss (10) also ran a series of intradermal tests using non-pregnant and pregnant females, males, females at menopause, postpartum women, cases of ectopic pregnancy and of abortion, as well as menstruating women. He concludes the test "is neither definite nor reliable." He states that in a private communication Porges and Pollatschek verified his conclusions, after they had used the test more extensively in Vienna.

I decided to attempt to repeat the work of Gilfillen and Gregg, using the technique as described by them. Further, it seemed wise to check the results with other anterior pituitary-like substances, and for this follutein and antophysin were chosen. A fourth injection for control, of sterile water with a few drops of glycerine, was made. Our technique consisted in thorough cleansing of both forearms, flexor surfaces, with sterile water. Two minims of each solution, antophysin, antuitrin-S, follutein, and glycerine-water, were injected intradermally, and the reaction ob-

determination of shock, it is easily conceivable that the loss of blood by the early tying of the cord might tend to increase an existing tendency to shock.

Chart 12 shows the result of selecting cases in which several of the favorable factors are present and another group in which the corresponding unfavorable factors are present. Group A represents a group of 32 cases born by non-cephalic presentation in which the duration of labor was over 12 hours in which the temperature never fell below 96 degrees, in which ether was administered for 15 minutes or more and in which the cord was not tied until pulsation had stopped. Group B represents a group of 35 cases born by cephalic presentation, in which the duration of labor was less than 12 hours, in which the temperature dropped below 97 degrees, in which ether was given for less than 15 minutes, and in which the cord was tied before pulsation had stopped. The weight curves speak for themselves. Group A lost weight only during the first 24 hours, the maximum loss being 3.53 per cent. From this point they recovered rapidly. On the fifth day (end of fourth day) they had practically recovered

their birth weight and on the eighth day, they were 1.76 per cent over birth weight. Group B lost much more during the first day, and continued to lose sharply during the second day, the maximum being 5.81 per cent. On the fifth day they were still 4.47 per cent below birth weight, considerably more than Group A on the second day. On the eighth day, they were still 2.55 per cent below birth weight.

SUMMARY

1. A statistical analysis of 996 newborn babies is presented with the view of determining whether obstetrical and neonatal procedures influence weight loss in the newborn.

2. It is shown that certain factors tend definitely to increase the loss in weight and that others tend to decrease the loss.

3. It seems conclusive that the weight loss of the newborn is not entirely "physiologic."

4. The evidence presented tends to confirm the idea, that the "normal" newborn is in a state of mild shock as a result of the trauma of labor.

5. In general, factors which tend to retard or ease the second stage of labor seem to be favorable to the child.

EVALUATION OF THE INTRADERMAL TEST FOR PREGNANCY

SUSANNE R. PARSONS, M.D., F.A.C.S., Santa Barbara, California

THE report of Gilfillen and Gregg on a "new, rapid, and economical" test for pregnancy which appeared in September, 1936, has led some of us to attempt to repeat their work. It seems worth while at this time to collect the data presented in the reports of these other workers and to add thereto a small series of tests which I have carried out.

An ideal test for pregnancy must meet certain requirements. It must first and foremost be at least 95 per cent accurate. It should be rapid, economical, and so simple that it may be available to workers lacking elaborate laboratory facilities. The Aschheim-Zondek test meets the first but requires several days and a large and always available supply of animals. Its various modifications offer little improvement in these respects.

Gilfillen and Gregg report that the skin test for pregnancy meets all the above requirements and in their hands they found it "proved more delicate than the Aschheim-Zondek test in border cases." The test is based on the idea that an anterior pituitary-like substance is present in the circulation of pregnant women, therefore these women would not be sensitive to this substance injected intradermally. Non-pregnant women would show a reaction, as it would not be present in the blood stream. Their technique consists of the intradermal injection of 2 minims of antuitrin-S in the flexor surface of the forearm, after it has been cleansed with sterile water. The reaction occurs usually within a few minutes, or may be delayed as long as 2 to 3 hours in elderly women. An area of erythema, 7 to 40 millimeters in diameter about the site of injection, develops in non-pregnant patients. In pregnancy no reaction occurs. They used the test not only for pregnancy, but in gynecological conditions, as abortion, ectopic pregnancy, hydatidiform mole, and teratoma of the ovary. A series of

24 controls, known non-pregnant patients, confirmed the accuracy of their test, which they state to be reliable in all these conditions.

Although Gilfillen and Gregg make no mention of the fact, this test was neither new nor original with them. It was first used by Porges and Pollatschek and reported before the Society for Internal Medicine in Vienna, March, 1929. Prolan was used and the readings were made the following day. This report was enthusiastic and it was claimed to be reliable in all cases but one, a woman with a hypophyseal tumor. No statement was made as to the number of cases tested, however.

Alfred Deutsch repeated this work on a series of 45 pregnant and 65 non-pregnant women. He concludes that there is no essential difference in skin reaction between the pregnant and non-pregnant. Only 11 of a series of 65 non-pregnant women gave a strong reaction. Strauss (10) also ran a series of intradermal tests using non-pregnant and pregnant females, males, females at menopause, postpartum women, cases of ectopic pregnancy and of abortion, as well as menstruating women. He concludes the test "is neither definite nor reliable." He states that in a private communication Porges and Pollatschek verified his conclusions, after they had used the test more extensively in Vienna.

I decided to attempt to repeat the work of Gilfillen and Gregg, using the technique as described by them. Further, it seemed wise to check the results with other anterior pituitary-like substances, and for this follutein and antophysin were chosen. A fourth injection for control, of sterile water with a few drops of glycerine, was made. Our technique consisted in thorough cleansing of both forearms, flexor surfaces, with sterile water. Two minims of each solution, antophysin, antuitrin-S, follutein, and glycerine-water, were injected intradermally, and the reaction ob-

determination of shock, it is easily conceivable that the loss of blood by the early tying of the cord might tend to increase an existing tendency to shock.

Chart 12 shows the result of selecting cases in which several of the favorable factors are present and another group in which the corresponding unfavorable factors are present. Group A represents a group of 32 cases born by non cephalic presentation in which the duration of labor was over 12 hours, in which the temperature never fell below 98 degrees, in which ether was administered for 15 minutes or more, and in which the cord was not tied until pulsation had stopped. Group B represents a group of 35 cases born by cephalic presentation, in which the duration of labor was less than 12 hours, in which the temperature dropped below 97 degrees, in which ether was given for less than 15 minutes, and in which the cord was tied before pulsation had stopped. The weight curves speak for themselves. Group A lost weight only during the first 24 hours, the maximum loss being 3.53 per cent. From this point they recovered rapidly. On the fifth day (end of fourth day) they had practically recovered

their birth weight and on the eighth day, they were 1.76 per cent over birth weight. Group B lost much more during the first day, and continued to lose sharply during the second day, the maximum being 5.81 per cent. On the fifth day, they were still 4.47 per cent below birth weight considerably more than Group A on the second day. On the eighth day, they were still 2.55 per cent below birth weight.

SUMMARY

1. A statistical analysis of 996 newborn babies is presented with the view of determining whether obstetrical and neonatal procedures influence weight loss in the newborn.

2. It is shown that certain factors tend definitely to increase the loss in weight and that others tend to decrease the loss.

3. It seems conclusive that the weight loss of the newborn is not entirely "physiologic."

4. The evidence presented tends to confirm the idea that the "normal" newborn is in a state of mild shock as a result of the trauma of labor.

5. In general, factors which tend to retard or ease the second stage of labor seem to be favorable to the child.

days postpartum, and duration of pregnancy have little influence on readings. Follutein was found to react more often both in the pregnant and non-pregnant groups, due perhaps to a protein reaction, rather than to the anterior pituitary-like hormone present.

Difficulty was experienced in making the readings, as pigmentation of the skin, and degrees of erythema were influencing factors, which often left me in doubt of the classification into which the test should fail. We have found this intradermal test thoroughly unreliable, and feel that it gives far too high a percentage of error for it to be trusted clinically. This is corroborated by the work of Strauss and Deutsch.

Gruskin reports the use of a placental extract which has been heated, with the result that the anterior pituitary-like gonadotropic fraction is destroyed. He claims good results.

In July, 1936, Schneider and Cohen report a series of 118 tests carried out on 95 females and 23 males. There were 21 pregnancies, 17 postpartum, or postabortal, 6 normal, and 74 with a wide variety of diagnoses. The results of the test showed 11 were not pregnant, 107 pregnant. Actually there were 21 pregnancies.

Isadore Gersh reports a series of 113 tests of which 50 were normal men and non-pregnant women; 48 were known cases of pregnancy of 2 or more months' duration and 15 were 1 to 9 days postpartum. In this series 3 injections were made, a control of normal saline with 0.5 phenol, antuitrin-S, and an anterior pituitary-like hormone extracted from placental tissue at the University of Colorado, Department of Pharmacology. The results of the tests show both false positive and false negative reactions. With antuitrin-S 20.8 per cent false negative results were obtained in the pregnant series and 6.6 per cent in the postpartum cases while 81.6 per cent of the men and 66.6 per cent of the non-pregnant women showed false positives. The control injection gave erythematous reactions in 8.8 per cent in 30 minutes and 5.4 per cent in 60 minutes.

Frank and Wahrsinger report a series of 198 cases. They used three different hormonal products, antuitrin-S¹, anterior pituitary

luteum² and progestin³. With antuitrin-S 163 cases were tested and showed that of 112 definitely pregnant women 28 gave positive skin reactions (non-pregnant reaction). Eight gave doubtful and 76 no reaction. This gave a 68 per cent accuracy. There were 21 postpartum women, all of whom gave strongly positive reactions. The second hormone was used in only 6 pregnant patients, 2 gave positive, 3 negative, 1 doubtful skin reactions. The third hormone was used in 29 cases and 10 known pregnant patients gave 9 positive skin reactions and 1 doubtful. The result of the entire series of 198 cases shows that 98 per cent of cases including pregnant women gave a positive skin reaction (non-pregnant).

Table I shows the results of the several series of cases presented by workers other than Gilfillen and Gregg.

TABLE I

	Total cases	Known pregnant	Non-pregnant	Positive skin reaction (non-pregnant)
Deutsch	110		65	11
Schneider	118	21		11
Gersh	113	48		20.8%
Frank and Wahrsinger	198	112		28
Parsons	140	100		34
Total	679			

These results show little variation with the use of different preparations of the hormone. Among those which have been used were antuitrin-S, an anterior pituitary-like hormone extracted from placental tissue⁴, anterior pituitary luteum, progestin, antiohophysin⁵, follutein⁶.

In conclusion, therefore, we may say the intradermal skin test, in 67.9 cases has proved entirely unreliable in the hands of all workers who have attempted to repeat the work of Gilfillen and Gregg. There seems to be no choice among the various hormonal preparations used; all yield equally unreliable results.

This work was done under a grant from the St. Francis Hospital Research Fund. The writer is indebted to the Santa Barbara General Hospital for generous use of material and also to the Nurses of St. Francis and Santa Barbara Cottage Hospitals for co-operation in making these tests.

¹Ayerst²Upjohn³University of Colorado⁴Winthrop⁵Squibb⁶Parke, Davis and Co

served at 15, 30, and, if no reaction had occurred by this time, again at 60 minutes. The solutions were made up freshly and kept on ice when not in use. A series of 140 women—100 known pregnant, 10 postpartum, and 30 known non pregnant patients—were tested. Careful note was made of the ages of the patients, the duration of pregnancy, and the time of the interval before reaction occurred. In the control group the relation to menstruation was noted, and in the postpartum group, the days since delivery. Our results were as follows:

In 100 cases of known pregnancy, no reaction with any of the solutions was shown in 66, in which group 1 ectopic is included, of the 34 cases which showed reaction 30 reacted with follutein only, 4 with all three solutions. Thus we see that follutein failed in 34 per cent, antuitrin S and antophysin in 4 per cent.

The possible influence of age was studied as follows. Of the total 100 patients, 29 were under 20 years of age, 56 were 21 to 30, 15 were 31 to 40. Of the 66 which showed no reaction, 18 were under 20, 38 were 21 to 30, and 10 were 31 to 40. Of the 30 reacting with follutein 9 were under 20, 17 were 21 to 30, and 4 were 31 to 40. Of the 4 reacting to all three solutions 2 were under 20, 1 was 21 to 30, and 1 was 31 to 40. These figures fail to show any evidence of age influence.

Studying the reaction from the standpoint of duration of pregnancy, we have 8 cases of pregnancy of 1 month's duration, 3 of 2 months, 8 of 3 months, 7 of 4 months, 7 of 5 months, 11 of 6 months, 18 of 7 months, 24 of 8 months, 12 of 9 months, 2 of 10 months.

In the 11 cases of 2 months or less duration, 8 reacted to one or more solutions, so that only 3 correct reactions were given. There were 4 who reacted to follutein alone and 4 who reacted to follutein, antuitrin S, and antophysin, but not to the control. In the cases of 3 months' duration, 5 showed no reaction with any solution, and 3 reacted only to follutein. Thus we see in the first 2 months the test proved incorrect in 72 per cent with all solutions. Almost one third error was shown in follutein alone and in foli-

tein, antuitrin S, and antophysin. As the duration of pregnancy increases, the percentage of error is reduced. The 3 month group showed that over 50 per cent gave positive pregnancy test.

The postpartum group gave the following results:

Number of cases	Days postpartum	Reaction
1	1	No reaction to 3 solutions
1	2	No reaction to 3 solutions
3	4	1 no reaction 1 to follutein 1 to antophysin
2	6	All reacted with follutein
1	9	No reaction to 3 solutions
2	10	All reacted to follutein only

Thirty controls of known non pregnant women were used, the ages varied from 19 to 50. In 6 of these there was no reaction observed with any of the solutions, or 20 per cent positive pregnancy test in known non pregnant individuals. In 15 there was a very faint reaction with follutein only. In 1 there was a definite reaction with follutein only. In 1 case both follutein and antuitrin S gave a faint reaction. Seven cases gave a definite reaction with all three solutions, and no reaction with the control injection. The ages of the 6 patients with no reaction were 19, 20, 21, 25, 37, 50. The ages in 7 with definite reaction were 21, 38, 30, 38, 35, 36, 26. The ages of the first group average 28 years, that of the second, 30 years, which slight difference could be of little significance in the result of the test.

The relation to menstruation, in the group of 6 with no reaction was 25, 30, 19, 10, 20 days past onset of last period. This shows little essential difference in the two groups.

In all groups studied, the reaction occurred promptly within 15 minutes, and in no case was it observed to show up as late as 30 minutes after the injection was made.

DISCUSSION

The intradermal test as shown by the foregoing figures gives a very unreliable test for pregnancy, since it is inaccurate in both the control group and in the known pregnant group with an error of from 4 to 72 per cent. In the early months of pregnancy when we particularly desire an accurate test, we find as high as 72 per cent error. Age, menstruation,

THE RÔLE OF TUBERCULOSIS IN ANAL FISTULA

LOUIS A. BUIE, M.D., NEWTON D. SMITH, M.D., and RAYMOND J. JACKMAN, M.D.,
Rochester, Minnesota

THIS study was undertaken in order to clarify, if possible, the controversy regarding tuberculosis as a cause of fistula-in-ano. Opinions have varied widely. Some believe that the majority of fistulas are of tuberculous origin; many feel that any relationship that may exist between anal fistula and tuberculosis is not significant. One probable reason why fistulas are considered to be of tuberculous origin is that healing often fails to occur following operation. Although a relationship between fistula-in-ano and phthisis was observed more than 2000 years ago, opinions then, as now, varied greatly. In early Roman literature (1) it was recorded that many patients who had anal fistula recovered promptly after operation but others did so slowly or not at all, and that many such patients died of "consumption." It was therefore believed that all fistulas drained infectious "humors" from the "system" and if closure were attempted disaster would result. Heurteloup actually advised the production of artificial fistulas in cases of consumption.

When we assumed our task, it appeared that there were five phases of the problem which required solution, namely: (1) What is a tuberculous anal fistula? (2) What percentage of anal fistulas are tuberculous? (3) In what percentage of cases of anal fistula is the tuberculous process a primary one? (4) What percentage of anal fistulas occurring among tuberculous patients are tuberculous? (5) If a tuberculous anal fistula is known to be present, should the treatment be altered?

Satisfactory answers are not available in the literature. The chief reason for the wide variation in opinions is that there is disagreement concerning what criteria are proper for the identification of a tuberculous anal fistula.

From the Section on Proctology, The Mayo Clinic, and The Division of Proctology, The Mayo Foundation. Abridgment of thesis submitted by Dr. Jackman to the Faculty of the Graduate School of the University of Minnesota in partial fulfillment of the requirements for the degree of Master of Science in Proctology.

REVIEW OF LITERATURE

A voluminous literature bears testimony to the difference of opinion on this subject. There are several reasons why the incidence of tuberculous anal fistula reported in the literature reviewed by us varies from 1.4 per cent to 61 per cent. Some studies were made in general hospitals; others were made in tuberculosis sanatoriums or in hospitals which had a special service for tuberculous patients. Often, histological or bacteriological study has not been made and systematic methods have not been used for diagnosis.

As to the frequency of pulmonary tuberculosis and co-existing anal fistula, figures quoted from various tuberculosis sanatoriums vary from 7 to 18 per cent. A wide variation is noted in the incidence of tuberculous fistula among patients who have pulmonary tuberculosis. Figures reported vary from 4 to 100 per cent.

What constitutes a tuberculous fistula and on what grounds are we justified in making a diagnosis? It is a discouraging task to attempt to correlate the findings of various investigators when the criteria on which the findings are based vary so greatly. There are two different methods which investigators have employed for determining a positive diagnosis: (1) that which depends on demonstration of the *Mycobacterium tuberculosis* by the inoculation of animals or by histological examination; (2) that which depends wholly on positive clinical findings. Between these two extremes are those who feel that demonstration of a certain histological picture is of diagnostic value. In addition to these factors, which partially account for the disparity in figures and diversity of opinion, is the difference in the material used for investigation. Attempts to demonstrate the tubercle bacillus in cultures made from the discharge of the ischio-rectal abscess have met with little success.

Gabriel's work proved satisfactorily that inoculation of animals is the diagnostic

a No 2 centrifuge with a head radius of 13.5 centimeters. Then the fluid was poured off and discarded and a portion of the sediment was removed, stained by methods for revealing acid-fast bacilli and studied for the presence of free tubercle bacilli. The remainder of the sediment was re-emulsified in 5 cubic centimeters of a normal saline solution. This product was placed in a refrigerator for 4 to 7 days to attenuate the colon bacillus, which is much more lethal to the guinea-pig than the staphylococcus or streptococcus. The colon bacillus also is the cause of the high proportion of failures in inoculating guinea-pigs with material taken from the lower portion of the gastro-intestinal tract.

Two guinea-pigs were given injections of material obtained from each patient, one animal being inoculated subcutaneously and the other intraperitoneally. If the guinea-pigs died and gross lesions were not evident before 3 weeks had passed, the test was considered a failure, if a guinea-pig died and lesions were not present after 3 or more weeks had elapsed, the result of the test was considered negative. If both animals were alive at the end of 4 weeks, the one receiving the intraperitoneal injection was tested by injecting 0.5 cubic centimeter of old tuberculin (O.T.) subcutaneously. If that guinea-pig died and the results of the test were positive, its mate was killed and examined. All other guinea-pigs were permitted to live for 8 weeks and, at the end of that time, were killed, and the result of the test was considered either positive or negative depending on whether lesions were present or absent.

Magath (5) has shown the importance of balancing the subcutaneously and intraperitoneally injected animals against each other. He pointed out that it is easy to understand why intraperitoneal injections should end fatally more often than subcutaneous injections, because much of the material injected contains pyogenic organisms, but, why this is true when equal amounts of the material are injected into each animal is not clear. Magath has also shown that tuberculin, although not productive of immediate death of each animal in which a positive result has been obtained, clearly

shortens the time necessary for the development of tuberculosis by about 3 weeks. In addition, Magath and Feldman (6) have demonstrated that more specimens will be found to contain the bacillus of tuberculosis by the method of injecting material into guinea-pigs than by the method of culturing the organism.

The possibility of obtaining false positive results from the inoculation of guinea-pigs may arise owing to spontaneous development of tuberculosis. Magath and Feldman have shown that when guinea-pigs are kept in cages in a room isolated from tuberculous animals and when they do not receive food from the tables of tuberculous patients and are cared for by non-tuberculous caretakers, the chances of their contracting tuberculosis is so slight that it may be ignored. Any such animal, if in normal health, may be considered suitable for experiments such as ours.

Some authors have questioned the reliability of results obtained by inoculation of guinea-pigs. Magath and Feldman stated that animals living 8 weeks after inoculation, in which gross lesions of tuberculosis have failed to develop, probably do not have tuberculosis and that the histological examination of such tissue is not necessary as a routine procedure. They concluded, after a careful study, that inoculation of guinea-pigs is a reliable means of proving the tuberculous nature of clinical material.

Fansler has expressed doubt as to the reliability of such a method when there is a focus of tuberculosis elsewhere in the body of the patient. In our series, we have avoided such error by performing repeated examinations of the sputum obtained from the patient and have compared the results of the inoculation of the guinea-pig with those of histological study. A piece of tissue almost invariably derived from the same specimen as that used for inoculation of animals was sent to the laboratory where routine pathological and histological studies were carried out.

In those cases in which the results of inoculation of animals were positive and those of routine histological study were negative, subsequent microscopic studies were made of sections cut from numerous blocks of tissue in

method which yields the most satisfactory results. He found that it is difficult to demonstrate tubercle bacilli in the tissues and he was unable to find the bacillus in any section prepared from tissue obtained from 6 patients who had been proved to have tuberculosis by the method of inoculation of animals. Moreover, in only 4 of the 75 cases which he studied did he find tubercle bacilli by using the staining method of Ziehl-Neelsen.

Tuberculous ulceration of the rectum does not occur frequently. In cases of fistula in ano, the tubercle bacillus gains entrance to the perianal tissues through a diseased crypt. The pathological characteristics of the tuberculous anal fistula are similar to those of tuberculosis elsewhere in the body excepting those changes which accompany secondary infection and trauma. Frequently, the attempt to make a clinical diagnosis or one based on the gross pathological characteristics of such a lesion is an error. The majority of such diagnoses are based on the appearance of the secondary, or external, openings. The appearance of the secondary opening may vary greatly, depending on the duration of the disease.

ROUTES OF INFECTION

In general, it is thought that there are four routes by which tubercle bacilli may gain access to the anorectal region.

Extension of infection from the lumen of the bowel. This is probably the usual route. The organisms gain entrance to the intestinal canal after they have been swallowed in the sputum. Tubercle bacilli, having passed through the digestive canal in this way, rarely produce tuberculosis in the anorectal region. Although tuberculosis of the intestine and rectum do occur and although tubercle bacilli are often found in feces, anorectal tuberculosis does not develop in the majority of the cases of pulmonary tuberculosis.

Transportation of organisms by the blood stream. According to this theory, tubercle bacilli are carried in the blood stream from some focus and are lodged in the submucous layer of the rectum and in the fat of the ischio-rectal fossa.

Direct external inoculation. Patients suffer from active pulmonary tuberculosis may

contaminate the anus, especially if an abrasion is present. This may result in direct inoculation of the abrasion with *Mycobacterium tuberculosis*.

Direct extension. Tuberculosis of the female genital organs, of the prostate gland or the seminal vesicles may produce a fistula which has an external opening near the anus. Similarly, tuberculosis of the sacrum, coccyx, or pelvic bones may involve the perirectal tissues and produce fistulas similar to anal fistulas.

Anal fistulas originate from infected anal crypts and rarely is the primary opening of such a fistula found elsewhere. In only 2 of the cases presented in this report was there an associated condition which suggested the possibility that tubercle bacilli had gained access to the ischio-anal or ischio-rectal tissues through avenues other than the crypts of Morgagni. Probably the most frequently offending organism in cases of ischio-rectal abscess is the colon bacillus.

Is the *Mycobacterium tuberculosis* a primary or secondary invader? It seems reasonable to regard tuberculous ischio-rectal conditions in the same light as tuberculous conditions of the thoracic wall. Primary tuberculous abscess of the thoracic wall is practically unknown.

METHOD OF STUDY

This investigation is based on 206 consecutive cases in which operation was performed for anal fistula. In addition to recording the patient's history and performing a physical examination, a roentgenological examination of the chest and routine laboratory tests of urine were carried out. Flocculation tests, determination of the concentration of hemoglobin, and of the number of erythrocytes and leucocytes also were performed. At the time of operation the surgeon paid particular attention to the selection of tissue that was to be subjected to examination and analysis.

Part of the selected tissue was prepared for inoculation into guinea pigs in the following manner. The tissue was finely divided by grinding and mixing with sand in a mortar. With this 5 cubic centimeters of normal saline solution was thoroughly mixed. The supernatant fluid was poured off and centrifuged for one hour at 2500 revolutions per minute in

TABLE I — SUMMARY OF A STUDY OF ANORECTAL FISTULA WITH REGARD TO ITS TUBERCULOUS NATURE—206 CONSECUTIVE CASES

	Cases	Per cent of cases successfully studied	Per cent total positive animal inoculations
Inoculation failed	11*		
Successfully studied	195†		
Negative in all respects for tuberculosis	163	83.6	
Evidence of tuberculosis somewhere in body	32	16.4	
Evidence of tuberculous "focus" but inoculation and histopathological examination negative	10	5.1

*5.3% of total cases 19.4% of total cases

tuberculosis could not be found microscopically. Frequently, foreign body giant cells are found in sections of tissue from anorectal fistulas and are sometimes confused with anatomic tubercle.

Ziehl-Neelsen staining technique was carried out on sections of tissue derived from all cases in which the result of inoculation of animals was positive and the bacillus of tuberculosis was identified in 3 cases (1.5 per cent of the total group or 13.6 per cent of the cases in which positive results were obtained on inoculation of animals).

Of the 22 patients who were proved to have a tuberculous fistula, 17 (87 per cent of those successfully studied and 77.3 per cent of those in which positive results were obtained by inoculation of animals) were shown to have, in addition, a so called focus of tuberculosis elsewhere in the body (9 cases of active pulmonary tuberculosis and 8 cases of a healed lesion in the lungs). In the 5 remaining cases of tuberculous fistula (2.5 per cent of those successfully studied and 22.7 per cent of those in which positive results were obtained by inoculation of animals), evidence of a "focus" of tuberculosis could not be found. In

1 of the 5 cases the organism was demonstrated in sections of tissue taken from the fistula.

Healing of the wound in cases of surgically treated tuberculous fistula is definitely prolonged. In the 22 cases in which positive results were obtained, the average time required for healing was 73 days as compared with an average of 29 days in the 173 cases of non-tuberculous fistula. Whether a fistula is tuberculous or not should not alter the type of treatment employed.

CONCLUSIONS

1. Inoculation of animals by the method described is the most accurate way of determining the tuberculous or non-tuberculous nature of an anorectal fistula.

2. In this series, positive results were obtained in 11.3 per cent of cases. Routine and also subsequent microscopic study of many sections of tissue proved that tuberculosis was present in only 6.6 per cent of the cases.

3. A tuberculous focus was present in 77.3 per cent of the cases of tuberculous fistula.

4. If pulmonary tuberculosis and anorectal fistula co-exist, the tuberculous nature of the fistula can be strongly suspected.

5. The co-existence of a focus of tuberculosis and non-tuberculous fistula occurred in 5.1 per cent of this series of cases.

6. Healing of the wound after operation is slower in cases of tuberculous fistulas than it is in those cases of non-tuberculous fistulas but healing should always be complete if the operation has been performed properly and if the wound has been dealt with adequately.

an effort to compare the results of histological study with those of inoculation of animals.

The staining technique of Ziehl Neelsen was used on sections of tissue in all cases in which the result of inoculation of the animal was positive.

RESULTS

In this study of 206 consecutive cases of anorectal fistula (Table I) there were 11 (5.3 per cent) in which both the animals that received subcutaneous injections and those that received intraperitoneal injections died before the aforementioned time limit had expired. Thus low percentage of failures can probably be accounted for by the fact that a method of attenuation of the colon bacillus was employed. More deaths occurred before the time limit expired in the cases of those guinea pigs injected intraperitoneally than occurred after the time limit had expired. However, as Magath has previously pointed out, a larger number of positive results are to be expected from the intraperitoneal method of injection than from the subcutaneous method of injection.

One hundred and ninety five cases (94.7 per cent of the total group) were studied successfully and completely. Of these evidence of the presence of tuberculosis was not found in 163 cases (83.6 per cent). In 32 cases (16.4 per cent) we were able to find evidence of the presence of tuberculosis somewhere in the body.

Of this group of 32 cases, 10 (5.1 per cent of total cases) gave evidence of a tuberculous "focus," that is, 7 of the patients had healed or inactive pulmonary tuberculosis, 2 had an active pulmonary lesion and 1 had tuberculosis of the cervical lymph nodes. Inoculation of animals, routine histopathological studies and subsequent study of numerous sections of tissue did not reveal evidence of tuberculosis in the anorectal fistula.

Inoculation of animals gave positive results in 22 cases (11.3 per cent of those successfully studied) whereas routine histological study of sections from an adjacent piece of fistulous tissue gave positive results in only 8 cases (4.1 per cent). These results approach closely those of other investigators who have used the same method of studying sections of a similar nature. If we had relied on routine histopathological study only, we would have missed the diagnosis in 63.6 per cent of the cases. In a subsequent study of numerous sections of tissue derived from those cases in which the diagnosis based on the results of inoculation of animals did not coincide with that based on routine histopathological examination we were able to demonstrate the presence of the tubercle in 5 additional cases (Figs 1 and 2). There were, therefore, 13 cases (6.6 per cent of total cases) in which the results of inoculation of animals coincided with those of microscopic study whereas in the remaining 9 cases (41.8 per cent of positive results) evidence of

CLINICAL SURGERY

FROM THE MANCHESTER ROYAL INFIRMARY

A MODIFIED SCHOEMAKER GASTRECTOMY FOR CHRONIC GASTRIC ULCER

JOHN MORLEY, Ch M, F R C S, Manchester, England

IN 1921, J. Schoemaker of the Hague described in *SURGERY, GYNECOLOGY AND OBSTETRICS* a modification of the original Billroth I gastrectomy that appeared to the present writer to obviate most of the difficulties and dangers of that operation.

After an extended trial of Schoemaker's operation it was realized that his original two bladed crushing clamp was often difficult to apply and prone to slip off the stomach when it had been applied, and in consequence a clamp of different type, that could be applied from the upper or lesser curvature aspect of the stomach, was designed for me by Dr K. B. Pinson, anesthetist to the Manchester Royal Infirmary.

The operation now to be described has been found to be superior to the Pólya-Balfour gastrectomy in cases of chronic gastric ulcer in that it is less likely to be followed by severe anemia, since some gastric function is preserved, while it involves no greater risk of anastomotic ulcer. In cases of duodenal ulcer with pronounced hyperchlorhydria, or in gastrojejunal ulcer, the more destructive Pólya-Balfour operation is preferred.

PREPARATION FOR OPERATION

The first essential is to see that dental sepsis is eradicated, and that the patient is provided with an efficient supply of teeth, natural or artificial, for the purpose of mastication.

When the roentgenographic examination shows appreciable delay in emptying, as is so commonly found in large prepyloric ulcers, gastric lavage for a few days, repeated on the morning of operation, is advisable. In cases of marked anemia from gross or continued occult hemorrhage, an intensive pre-operative course of iron is essential.

THE ANESTHETIC

While some surgeons are strong advocates of a combination of local and splanchnic anesthesia, we have found that basal anesthesia with avertin,

followed by gas and oxygen with some ether, is less trying to the patient and the surgeon, less time-consuming, and no more dangerous as regards postoperative complications. The services of a really expert anesthetist are, of course, essential.

THE OPERATION

A right paramedian incision extending from the costal margin to a little below the umbilicus, is usually preferred, as it gives a stronger scar and affords the best access to the duodenum. The edges of the wound are then protected by gauze swabs. After a general inspection of the abdominal viscera, including the stomach and duodenum, the thin lesser omentum is torn through above the prepyloric portion of the stomach and a hand is inserted into the lesser sac of the peritoneum to separate the filmy congenital adhesions so constantly found between the stomach and the transverse mesocolon or colon. The pyloric vessels immediately above the first part of the duodenum are then clamped between two artery forceps, divided and ligatured with linen thread. The gastroduodenal ligament is next divided between forceps, beginning just below the pylorus and working as far to the left as the point at which it is decided to divide the stomach. All the lower divided vessels are then tied, those on the upper or gastric side being left in the grip of the artery forceps. The line of this division may be carried immediately below the greater curvature of the stomach and above the gastro-epiploic vessels, or between the gastro-epiploic vessels and the transverse colon, in which case the right gastro-epiploic artery is divided below the pyloric antrum. While the former method has the theoretical advantage that it preserves the blood supply of the dependent portion of the omentum, it involves the ligation of many more vessels than the latter. We prefer to divide the omentum below the gastro-epiploic vessels on this account and have found no ill effects upon the omentum in practice. The

Fig 1 Method of applying the author's crushing clamp. The duodenum has been divided between clamps and the crushing clamp and a Schoemaker colectomy for cecum are applied to the stomach. Note. Considerably more of the stomach is usually removed than this illustration depicts.

Fig 2 One blade of the crushing clamp has been removed and the continuous hemostatic suture along the new lesser curvature is being inserted.

Fig 8 The operation completed Note the normal form of the stomach

Fig 3 Application of the invaginating seromuscular suture along the new lesser curvature

left gastro epiploic vessels are clamped, divided, and tied at a point as far to the left as is necessary. The next step is the division of the first part of the duodenum. Two Schoemaker colectomy clamps with grooved blades are applied side by side across the duodenum immediately distal to the pyloric sphincter and the duodenum is divided between them with a knife. The cut ends of the duodenum held by the two clamps are cleaned with moist swabs. The distal clamp is left covered by a large gauze swab and the proximal clamp is protected by a small gauze swab clamped over it by two Lane's tissue forceps. These forceps not only prevent any risk that the Schoemaker clamp may slip but are convenient in exerting traction on the stomach.

The stomach is now lifted up and to the left and any adhesions between the ulcer and the pancreas are divided. When the ulcer is not penetrating the pancreas this division is carried out with the knife. In large ulcers that have invaded the pancreas deeply however it is unsafe to cut into the pancreas on account of the risk of subsequent leakage of pancreatic juice. In such cases the edges of the ulcer are stripped off the pancreas with the fingers regardless of the fact that the lumen of the stomach is opened. Swabs are placed round before this maneuver and a sucker is inserted into the stomach to empty it of any fluid contents. The line of cleavage where the ulcer is stripped off the pancreas is avascular and does not bleed.

Having freed the ulcer from its posterior adhesions the left gastric (coronary) artery in the gastrohepatic omentum is divided between clamps. This is done a short distance above the ulcer on the lesser curvature. A hole is made between the lesser curvature of the stomach and the lesser omentum and three curved artery for-

ceps are applied to the upper part of the lesser omentum through this hole so as to grasp the left gastric artery. The omentum and artery are divided by curved scissors, two of the artery forceps being left on the proximal part of the artery and one on the distal part. The proximal end is then doubly ligatured with No. 60 linen thread and the distal end is also tied.

The stomach is now drawn downward and out of the wound and the point on the greater curvature destined for anastomosis with the duodenum is determined. Here a Schoemaker colectomy clamp is applied at a right angle to the greater curvature, with care to include as much of the transverse section of the stomach in its grip as will correspond with the width of the duodenum.

While an assistant draws the stomach firmly downward and also exerts some downward traction on the colectomy clamp that grasps the greater curvature of the stomach the curved Pinson crushing clamp is applied to the stomach from the lesser curvature above the ulcer a little obliquely so that the tip of its blades touches the tip of the small colectomy clamp (Fig. 1). A straight or curved gastro-enterostomy clamp is now placed across the stomach distal to these two clamps to prevent escape of contents and the stomach is divided with a knife flush with the two proximal clamps and its distal portion is removed.

The next step is closure of that part of the stomach in the grip of the large two bladed crushing clamp to form what is to be the new lower portion of the lesser curvature. The outer blade of the crushing clamp is removed leaving a frill of crushed stomach wall projecting from the inner blade. This stomach wall is sutured with a continuous stitch of No. 00 catgut (20 day) starting at the tip of the blade and working up to the lesser curvature (Fig. 2). The second blade of the

SUPRACONDYLAR FRACTURE OF THE HUMERUS

An Analysis of 330 Cases

IRWIN E. SIRIS, M D., Brooklyn, New York

THE purpose of this paper is the review of the results of treatment of 330 cases of supracondylar fractures of the humerus which have been seen on the Children's Surgical Service of Bellevue Hospital during the past 18 years. The 109 cases of supracondylar fracture that were reported in 1925 (8) are included in this report. Certain fundamental problems presented themselves in the management of these cases which will be discussed in this paper. A method of reduction and fixation is described so as to prevent deviation of the axis of the forearm. It is not the purpose to review the literature of supracondylar fracture but rather to present the salient clinical problems which have been encountered in the treatment of these cases.

Supracondylar fracture is a distinct entity having little in common with fractures in other parts of the body. This is particularly so for the following reasons: first, because of the close proximity of the fracture to the intricate articular surface of the elbow joint, second, the effect that the displacement of the fragments may have on the neurovascular structures passing over the joint, third, the possible permanent deviation of the axis of the forearm that may result from (a) an injury to the cartilage plate of one of the epiphyses, or (b) a failure to obtain a correct alignment of the distal fragment of a supracondylar fracture.

END-RESULTS

Of the 330 cases of supracondylar fractures treated, 292 (89 per cent) of the patients were followed from 2 months to as long as 14 years, and 38 were lost.

The factors which were considered in evaluating the results, are (1) restoration of function, (2) deformity, and (3) residual complications.

1 Restoration of function. Of the 292 cases, 236 (81 per cent) had almost complete restoration of function. Of the 56 remaining cases (19 per cent), 4, complicated by threatened ischemic paralysis, have not regained complete function, and in 52 others (18 per cent) the functional recovery is protracted and the patients are under treatment.

From the Children's Surgical Service, Bellevue Hospital, Fenwick Beekman, M. D., in charge

2 Deformity. There were 44 of the 236 cases which regained function, and in these cases there was deviation of the axis of the forearm, 26 having a loss in the carrying angle, 8 with a glaring *gunstock deformity*. In 2 cases the deformity has been corrected by a cuneiform osteotomy. Nineteen fractures healed with a perceptible increase in the outward angulation of the forearm. It is significant that the reparative process in children due to growth often corrects a deformity caused by a vicious union but does not always restore the normal carrying angle. In this series vicious union rarely permanently impaired function, while an unreduced lateral or mesial fracture or rotation of the distal fragment invariably altered the carrying angle.

3 Residual complications. There were 20 cases of muscular spasm and 7 of myositis ossificans. Both of these complications followed fractures about the elbow which were recorded in my previous paper. In the case of the 221 patients with supracondylar fracture which have been treated since 1924, when the former series was reported, there has been no case of either muscular spasm or myositis ossificans. In but 1 of the 9 cases which showed evidence of an impending Volkmann's ischemic paralysis did ischemia develop. Seven children had symptoms referable to injury of the deep muscular branch of the radial nerve and 4 of the ulnar nerve. Whether this resulted from a displaced fragment or excessive callus formation accompanying vicious union is uncertain, but it is interesting to note that the symptoms in all of these cases of nerve injury have disappeared as a result of the absorption of the excessive callus. No case of delayed ulnar neuritis has come under our observation as yet in this series.

The following classification has been adhered to in the analysis of the end-results

Excellent	—Complete function with a normal carrying angle
Good	—Complete function with a slight increase in the carrying angle
Fair	—Complete function with a 5 per cent loss of carrying angle
	—Limitation of less than 25 per cent flexion with a straight or normal axis of the forearm

clamp is now removed, and a continuous seromuscular suture of catgut is inserted so as to invaginate the former or through and through suture (Figs 3 and 4).

The two small colectomy clamps, one on the duodenum and one on the greater curvature of the stomach, can now be approximated with the greatest of ease for the end to-end anastomosis of the stomach with the duodenum. The posterior part of the continuous seromuscular catgut stitch is begun at the lesser curvature aspect. A curved needle is used and it is inserted parallel with the clamps (Fig 5). When the greater curvature is reached, the suture is knotted and laid aside.

Before the colectomy clamps occluding the stomach and duodenum are removed these organs are secured by two gastro-enterostomy clamps placed one inch above and below the line of anastomosis. The occluding clamps are now removed and the continuous through and through catgut suture is inserted again on a curved needle (Figs 6 and 7).

The seromuscular suture is next completed by carrying it along the anterior surface of the suture line up to the point at the lesser curvature where it started. After the circle is completed and the suture is tied, two further sutures are inserted to guard the 'dangerous angle' on the lesser curvature from tension. We have never known leakage to occur at this or any other point.

In performing this end to end anastomosis it is important to make sure that no stenosis results. The finger and thumb should be able to meet readily when invaginating the anastomosis from without at completion of the operation (Fig 8).

One point in the application of the crushing clamp requires emphasis. The clamp should never be applied too obliquely so as to make the

new prepyloric portion of the stomach too slender and funnel shaped. In earlier cases in which this was done, some disturbing postoperative vomiting occurred for the first few days. When the clamp is applied as it should be almost transversely to the stomach, the postoperative course is usually free from vomiting. The abdominal wound is closed in layers in the usual way and a dressing applied.

POSTOPERATIVE TREATMENT

Morphia and atropine and rectal saline infusions are given for the first 24 hours. Intravenous saline by the continuous drip method is reserved for cases suffering from pre operative anemia or for those rare patients who develop symptoms of postoperative shock. Fluids sufficient to allay thirst are allowed from the first. A daily enema is given from the second day until the end of the first week. No solid food is allowed until a week from the operation has elapsed. The postoperative course is usually smoother than that after a simple gastro-enterostomy in that there is less tendency to vomiting.

MORTALITY RATE

In a consecutive series of 190 cases of Schaeffer gastrectomy for chronic gastric ulcer in which patients were operated upon by the writer, there have been 5 deaths a mortality of 2.6 per cent. This is little above the mortality of gastro-enterostomy for simple ulcer and compares favorably with the mortality of the Balfour-Polya operation in the same type of case, which has been 6.4 per cent in my hands.

I am indebted to the publishers of the *British Journal of Surgery* for the loan of the illustrations. These drawings were reproduced to appear in an article on 'The Technique and Results of Partial Gastrectomy for Chronic Gastric Ulcer' 19 8 16 239-5.

Fig 2 a, b, c, Steps in procedure for reducing the lateral or mesial and posterior displacement of the distal fragment

fragment can still be seen to project obliquely forward

The stripping of the periosteum from the distal end of the upper fragment can be demonstrated by means of a lateral view as early as the seventh day after the fracture in practically every case in which the fracture has not been completely reduced. Ordinarily the stripped periosteum which is firmly attached to the displaced lower fragment is not visualized, for only after the deposition of calcium in the callus can the new shaft be discerned within the confines of the stripped periosteum

DISPLACEMENT OF FRAGMENTS

Supracondylar fracture continues to be the most frequently encountered elbow injury on the Children's Surgical Service at Bellevue Hospital. In all the cases in which the distal fragment was displaced posteriorly, the trauma producing the injury was from a fall on the outstretched hand. The displacement resulted in a stripping of the periosteum from the distal end of the proximal fragment due to its firm attachment to the distal fragment. This was first noted by Poland in 1898, who drew attention to it as an important factor in the production of callus. This stripping of the periosteum plays an important part in limiting the displacement of the fragment and in subsequent healing, particularly when complete reduction has not been obtained. This may be demonstrated in 3 to 6 weeks' time by means of a roentgenogram, which then shows evidence of new bone springing from the displaced lower fragment and along the reflected periosteum.

In 72 cases (22 per cent) there was no displacement of the lower fragment. Of the 244 cases

(74 per cent), in which complete *posterior* displacement of the lower fragment was present, 162 had no appreciable lateral or mesial displacement, in 44 the lower fragment was displaced backward and inward and in 38 backward and outward. The lower fragment was displaced *anteriorly* in but 14 cases (4 per cent) all of which fractures were sustained through direct violence.

There were 232 fractures in which the line of fracture was transverse and 98 in which it was oblique. With the few exceptions in the case of oblique fractures the distal end of the proximal fragment was displaced into the antecubital space. Of the 330 fractures 33 were comminuted. Thirty-two extended into the external condyle, 39 into the internal condyle, and 21 through one of the epiphyseal cartilage plates.

In two of the comminuted fractures the articular fragment was split, a consequence of muscle contraction which forces the upper fragment between the lower fragments, thus distorting the elbow joint.

TREATMENT

There are four important objectives to bear in mind in the treatment of a supracondylar fracture. First and foremost is the prevention of a Volkmann's paralysis, second, a satisfactory reduction, third, the prevention of a varus or valgus deformity, and fourth, the restoration of function. All four objectives are dependent on obtaining a good alignment of the fragments. Permitting the malposition of the fragments to remain until the swelling has subsided is unreasonable. Such a procedure necessitates a difficult and prolonged course of treatment and a defeat in one or more of the objectives. The malposition should

Fig 1 Typical supracondylar deformity with posterior displacement of the distal fragment

- | | |
|------|--|
| Poor | —Complete function and an obvious gun stock deformity |
| | —Limitation of less than 5 per cent extension and flexion of the elbow |
| Bad | —More than 25 per cent limitation of function |
| | —Volkmann's ischemic paralysis |
| | —Ankylosis |

Of the 292 cases followed, in 168 (58 per cent) the results can be said to be excellent, 30 (10 per cent), good, 69 (24 per cent), fair, 15 (5 per cent), poor, and 10 (3 per cent), bad. These results include the 52 cases (18 per cent) in which patients are under treatment, and in many of them there will be improvement in function and the cases therefore deserve better classification.

AGE INCIDENCE

It is significant that the largest number of cases occurred during the sixth year and that between the ages of 5 and 7 there were 16 (49 per cent). This being almost equal to the combined number of fractures occurring in the 9 remaining age groups of this series. The incidence of frequency in the various age groups appears to decrease both toward earlier childhood and the advancing years.

CLINICAL EXAMINATION

Of the 258 supracondylar fractures with displacement, the distortion from swelling increased perceptibly in proportion to the delay supervening between the time of injury and that of reduction (Fig 1). In many of these the lower end of

the anteriorly displaced upper fragment could readily be palpated beneath the skin. The break in the continuity of the humerus could often be palpated posteriorly. Due to this displacement and the extravasation of blood in the antecubital space, there was often much tension of the overlying skin which at times was followed by the formation of blebs. In most of the cases the forearm assumed a position of complete pronation with approximately 140 degrees of extension at the elbow joint. When the fragments were completely displaced there was always an increase in the anterior posterior diameter of the arm.

When there was overriding measurements taken from the tip of the acromial process to the lateral epicondyle revealed an appreciable shortening as compared with the other arm. In none of these cases was there any disturbance in the relation between the three bony prominences of the elbow; this finding was indispensable in eliminating a posterior dislocation of the radius and ulna. *The presence or absence of neurovascular injury should be noted before any attempt is made to reduce the fracture so as to obviate a later question of such complications having resulted from the manipulation.* There were 12 compound fractures in this series, which are detailed elsewhere.

ROENTGENOGRAPHIC EXAMINATION

Roentgenographic examination should determine not only the extent of the displacement of the lower fragment but also whether there is an extension of the fracture line through the epiphyseal cartilage plate of either of the condyles. The amount of serration or spurring of the fracture surface should be noted, because of its influence upon attempts at reduction.

What at first appearance may seem to be a transverse fracture will occasionally be found to be a fracture line which extends obliquely downward and forward. This is the type of fracture that is so difficult to maintain in position after reduction. It is important to note the amount of lateral or mesial displacement of the lower fragment as failure to recognize and correct this displacement will result in a varus or valgus deformity.

A lateral view will reveal the amount of anterior displacement of the upper fragment. The relationship of the distal fragment and the forearm which are one to the upper fragment in regard to the amount of rotation of the lower fragment, is often demonstrable in this view. The significance of the rotation of the lower fragment on the upper is appreciated after the posterior displacement has been reduced when the upper

Fig 2 a, b, c, Steps in procedure for reducing the lateral or mesial and posterior displacement of the distal fragment

fragment can still be seen to project obliquely forward

The stripping of the periosteum from the distal end of the upper fragment can be demonstrated by means of a lateral view as early as the seventh day after the fracture in practically every case in which the fracture has not been completely reduced. Ordinarily the stripped periosteum which is firmly attached to the displaced lower fragment is not visualized, for only after the deposition of calcium in the callus can the new shaft be discerned within the confines of the stripped periosteum.

DISPLACEMENT OF FRAGMENTS

Supracondylar fracture continues to be the most frequently encountered elbow injury on the Children's Surgical Service at Bellevue Hospital. In all the cases in which the distal fragment was displaced posteriorly, the trauma producing the injury was from a fall on the outstretched hand. The displacement resulted in a stripping of the periosteum from the distal end of the proximal fragment due to its firm attachment to the distal fragment. This was first noted by Poland in 1898, who drew attention to it as an important factor in the production of callus. This stripping of the periosteum plays an important part in limiting the displacement of the fragment and in subsequent healing, particularly when complete reduction has not been obtained. This may be demonstrated in 3 to 6 weeks' time by means of a roentgenogram, which then shows evidence of new bone springing from the displaced lower fragment and along the reflected periosteum.

In 72 cases (22 per cent) there was no displacement of the lower fragment. Of the 244 cases

(74 per cent), in which complete *posterior* displacement of the lower fragment was present, 162 had no appreciable lateral or mesial displacement, in 44 the lower fragment was displaced backward and inward and in 38 backward and outward. The lower fragment was displaced *anteriorly* in but 14 cases (4 per cent) all of which fractures were sustained through direct violence.

There were 232 fractures in which the line of fracture was transverse and 98 in which it was oblique. With the few exceptions in the case of oblique fractures the distal end of the proximal fragment was displaced into the antecubital space. Of the 330 fractures 33 were comminuted. Thirty-two extended into the external condyle, 39 into the internal condyle, and 21 through one of the epiphyseal cartilage plates.

In two of the comminuted fractures the articular fragment was split, a consequence of muscle contraction which forces the upper fragment between the lower fragments, thus distorting the elbow joint.

TREATMENT

There are four important objectives to bear in mind in the treatment of a supracondylar fracture. First and foremost is the prevention of a Volkmann's paralysis, second, a satisfactory reduction, third, the prevention of a varus or valgus deformity, and fourth, the restoration of function. All four objectives are dependent on obtaining a good alignment of the fragments. Permitting the malposition of the fragments to remain until the swelling has subsided is unreasonable. Such a procedure necessitates a difficult and prolonged course of treatment and a defeat in one or more of the objectives. The malposition should

Fig. 1 Typical supracondylar deformity with posterior displacement of the distal fragment

|------|---|
| Poor | —Complete function and an obvious gun stock deformity |
| | —Limitation of less than 25 per cent extension and flexion of the elbow |
| Bad | —More than 25 per cent limitation of function |
| | —Volkmann's ischemic paralysis |
| | —Ankylosis |

Of the 292 cases followed in 168 (58 per cent) the results can be said to be excellent 30 (10 per cent), good 69 (24 per cent) fair 15 (5 per cent), poor and 10 (3 per cent) bad. These results include the 52 cases (18 per cent) in which patients are under treatment and in many of them there will be improvement in function and the cases therefore deserve better classification.

AGE INCIDENCE

It is significant that the largest number of cases occurred during the sixth year and that between the ages of 5 and 7 there were 162 (49 per cent). This being almost equal to the combined number of fractures occurring in the 9 remaining age groups of this series. The incidence of frequency in the various age groups appears to decrease both toward earlier childhood and the advancing years.

CLINICAL EXAMINATION

Of the 258 supracondylar fractures with displacement, the distortion from swelling increased perceptibly in proportion to the delay supervening between the time of injury and that of reduction (Fig. 1). In many of these the lower end of

the anteriorly displaced upper fragment could readily be palpated beneath the skin. The break in the continuity of the humerus could often be palpated posteriorly. Due to this displacement and the extravasation of blood in the antecubital space there was often much tension on the overlying skin which at times was followed by the formation of blebs. In most of the cases the forearm assumed a position of complete pronation with approximately 140 degrees of extension at the elbow joint. When the fragments were completely displaced there was always an increase in the anterior posterior diameter of the arm.

When there was overriding, measurements taken from the tip of the acromial process to the lateral epicondyle revealed an appreciable shortening as compared with the other arm. In none of these cases was there any disturbance in the relation between the three bony prominences of the elbow; this finding was indispensable in eliminating a posterior dislocation of the radius and ulna. *The presence or absence of neurovascular injury should be noted before any attempt is made to reduce the fracture so as to obviate a later question of such complications having resulted from the manipulation.* There were 12 compound fractures in this series, which are detailed elsewhere.

ROENTGENOGRAPHIC EXAMINATION

Roentgenographic examination should determine not only the extent of the displacement of the lower fragment but also whether there is an extension of the fracture line through the epiphyseal cartilage plate of either of the condyles. The amount of serration or spurring of the fracture surface should be noted, because of its influence upon attempts at reduction.

What at first appearance may seem to be a transverse fracture will occasionally be found to be a fracture line which extends obliquely downward and forward. This is the type of fracture that is so difficult to maintain in position after reduction. It is important to note the amount of lateral or mesial displacement of the lower fragment as failure to recognize and correct this displacement will result in a varus or valgus deformity.

A lateral view will reveal the amount of anterior displacement of the upper fragment. The relationship of the distal fragment and the forearm which are one to the upper fragment in regard to the amount of rotation of the lower fragment is often demonstrable in this view. The significance of the rotation of the lower fragment on the upper is appreciated after the posterior displacement has been reduced when the upper

Reducing the posterior displacement of the distal fragment. (x) Correction of the lateral or mesial displacement is equally as important as the or-

rection of the posterior Gentle pressure with the thumb and index finger on both sides of the fragments aligns the ends of the bone in the proper

Fig 11 R Q 7 years old a, June 23 1931, impaction and forward angulation of both fragments b, Note slight lateral displacement of the distal fragment Reduction was unsuccessful and when the elbow was immobilized in acute flexion in plaster molded splints, the radial pulse became obliterated and the fingers began to swell The splints were removed and the forearm was suspended at right angles to the elbow This was followed by a restoration of the radial pulsation c, July 13, 1931, correction of the lateral displacement of the distal fragment is shown d, July 13, 1931, lateral view Note persistent backward displacement of the distal fragment with periosteal stripping and vicious union with evidence of a new shaft forming e, November 23, 1932, lateral view Note recession of protruding upper fragment and extent of reparative process in 7 months f, November 23, 1932, anterior view An appreciable downward growth of the mesial aspect of the lower end of the humerus with a deviation of the axis of the forearm is revealed Junction of the elbow was entirely regained but there was a perceptible increase in the carrying angle

of the upper fragment, hyperextension of the elbow is brought about by traction upon the patient's pronated wrist with the surgeon's left hand while the operator's right thumb exerts downward and forward pressure on the posterior aspect of the lower fragment simultaneously as pressure is exerted on the anterior aspect of the upper fragment by the four fingers of the surgeon's right hand (Fig 2b) This maneuver results in the distal fragment gliding under the proximal With the thumb and four fingers of the right hand maintaining pressure upon the lower and upper fragments respectively, the patient's forearm is brought into a position of *acute flexion and the forearm is semipronated* (Fig 2c) The position of the fragments is now checked by means of the fluoroscope

If a fluoroscope is not available, lateral and anteroposterior roentgenograms should be obtained before the retentive dressing is applied These maneuvers should be repeated if a satisfactory reduction of the fragments has not been obtained The use of force during manipulation is contra-indicated lest the serrations upon the ends of the fragments be destroyed or damage be inflicted to the soft parts

What constitutes a satisfactory reduction? Obviously a normal re-alignment means a satisfactory position of the fragments, this should result in an early functional recovery without deformity (Fig 3, Case L K—a, b, c, d, e)

A partial reduction of a posteriorly displaced lower fragment is satisfactory provided the rotation has been corrected and there is no mesial or lateral displacement. For example, in the case of

L C (Fig 4 a, b, c, d), the displaced lower fragment became the base of the new shaft as the reparative process developed within the confines of the periosteum which had been stripped off the posterior aspect of the upper fragment and the end of the anterior displaced upper fragment became absorbed and receded as the lower fragment continued to grow downward In this way the contour of the shaft of the humerus assumed a normal appearance, there was no deviation of carrying angle, and functional recovery was restored with no disability

A persistent overriding or a lateral or mesial displacement must be considered as unsatisfac-

Fig 12 Skeleton traction The Kirschner wire is inserted through the base of the olecranon process, distal to the epiphysis Balanced traction is made with the forearm in a position of flexion and semipronation

Fig 7 Immobilization in molded plaster splints. a Flexion and semipronation with crescentic opening for palpation of radial pulse. b Splints bandaged and forearm across the chest. Sling is omitted to show the unplastered wrist to permit access to the radial pulse.

long axis of the humerus (Fig 2a). Failure to recognize and reduce the lateral or mesial displacement will result in a varus or valgus deformity for which even the extraordinary reparative process, due to the growth of bone, will often fail to compensate. Too much emphasis, therefore, cannot be placed on the importance of correcting the lateral slide even though the posterior displacement has been reduced.

If the fragments are *partially impacted* and there is a *lateral displacement*, the *impaction should be broken up* by means of *rocking* the fragments. Rocking has been used by the writer for many years for breaking up impactions.

(2) The posterior displacement of the lower fragment is corrected by means of hyperextending the elbow and exerting a downward pressure on the lower fragment as advocated by Lusk, then the elbow is flexed as recommended by Jones and the forearm is pronated as suggested by Boehler.

Fig 9 C H. a Myositis ossificans resulting from kneading massage. b Three years after discontinuing massage.

Fig 8 Non-constricting adhesive fixation dressing with the forearm flexed and in semipronation. a A wide strip of adhesive is placed on the ulnar side of the volar surface of the forearm close to the wrist, extending behind the mesial aspect of the semipronated forearm along the outer side and back of the arm close to the axilla and over several layers of gauze which extends above and below the adhesive. b The adhesive is continued over the inner side of the arm and forearm. (Note that the radial half of the forearm and part of the arm are not covered with adhesive; that is there is no encircling dressing and access to the radial pulse is easy.) c A thinly padded basswood splint is applied to the back of the forearm beginning from the metacarpal phalangeal junction to the elbow to prevent a pseudo wrist drop. The forearm rests across the chest and is suspended from the neck by a sling which is loosely tied about the wrist so as to avoid constriction.

These principles for reduction and fixation and the rocking of the elbow to correct the lateral displacement of the fragments are carried out in the following manner. Rocking is accomplished by grasping the pronated wrist and raising the forearm; the elbow is then rocked in all directions. This procedure invariably unlocks any impaction and with the aid of a little pressure the fragments become aligned in their long axis. To obtain reduction of a fracture of the left arm the surgeon stands to the left of the patient and with his left hand grasps the patient's pronated wrist. With the thumb of the right hand behind the lower fragment and the remaining four fingers in front

FIXATION OF FRAGMENTS

Reduction and fixation of the fragments in this series were obtained by the following methods

- 1 Reduction and immobilization in molded splints of plaster of Paris
- 2 Reduction, adhesive plaster dressing, followed by early mobilization
- 3 Suspension for unsuccessfully reduced fractures with or without compression of the neurovascular structures
- 4 Immobilization in a Thomas splint in the treatment of compound fractures
- 5 Skeleton traction by means of a Kirschner wire through the olecranon for "T" or "Y" shaped fractures and in the treatment of compound fractures
- 6 Open operation

tory as persistent overriding of the fragments may cause (a) Volkmann's ischemic paralysis, or (b) vicious union. With exuberant callus vicious union impairs function or delays functional recovery. I believe that every surgeon has at one time seen such a case where persistent overriding of the fragments has caused the formation of vicious union which later with the absorption of the exuberant callus has resulted in a complete anatomical and functional recovery (Case 1, V.S. Fig 5 a b, c d e f). Not all such cases will

necessarily result in complete restoration of function. Some may have residual deformity or a limitation in function. To permit the fragments to remain overriding with the thought that the ultimate results may be satisfactory is beset with danger and is not to be recommended.

A correction of the posterior displacement of the lower fragment without a complete reduction of the lateral or mesial displacement may result in a varus or valgus deformity which can be corrected only by means of a cuneiform osteotomy

Fig 14 J.Z. a August 19 1931 after two attempts to replace fragment some posterior angulation persists b October 17 1931 inward displacement of the lower fragment not completely reduced periosteal stripping and a new shaft in process of formation with downward growth of outer aspect of lower end of the humerus c April 10 1937 5 1/2 years later. Some varus deformity present but function is complete

Fig 19 H W, 9 years old a, April 28, 1936, transcondylar fracture extending above internal epicondyle across the external condyle b, Line through middle of long axis of shaft of humerus passes well behind the posterior border of capitellum instead of about one-third of the capitellum being behind the plane c and d, September 16, 1937, premature ossification of the cartilage plate of the capitellum and external condyle with continued function of trochlea causing an outward deviation of the forearm as contrasted to the normal elbow e, Photograph September 16, 1937, indicating the extent of outward deviation of the axis of the forearm

tion of flexion with the forearm supinated. This method has subsequently been modified by placing the forearm in a position of semipronation (Fig. 8 a, b, c) as it was observed that in the earlier cases the forearm invariably assumed a pronated position irrespective of the efforts made to retain it in a position of supination, and as this pronated position relaxes the flexor-pronator group of muscles the danger is lessened of a recurrence of the displacement which may result in a change of the carrying angle.

The advantage of the adhesive plaster dressing over plaster splints is that the patient can actively exercise the elbow during the entire period of immobilization, and in this manner stimulate the absorption of the extravasated blood and prevent muscular atrophy. The return of function is thus hastened. These active motions can be taken within the confines of the dressing and as the swelling subsides the dressing can be re-applied from time to time so as to increase the range of motion. As in the case of immobilization by splints, forced motion is contra-indicated. At the end of the third week after the dressing has

been finally removed, the range of motion can be further increased. Complete function should be regained in from 6 to 12 weeks following the accident.

It has been observed that in the cases in which the elbow has been completely immobilized for too long a time, as in a plaster splint, the return of function is delayed for a longer period than in the cases in which incomplete mobilization for a similar period by means of adhesive plaster dressing has been used.

Physiotherapy was formerly used but we have discontinued it as it was observed that in those cases in which massage and other means of physiotherapy were used the structures about the elbow became more rigid, thereby increasing the time before function was restored. In some of these cases bony changes occurred in the muscles, a myositis ossificans traumatica (Fig 9). We have recently therefore used only active motion by means of occupational therapy which has given better results.

The objection to adhesive plaster dressing and the reason for reverting to the use of plaster splints lie in the fact that the dressings so fre-

Fig 16 I M 6 years old a June 11 1931 comminuted fracture extending into mesial epiphysis inner fragment rotated anteriorly and displaced forward (Un-

beyond a right angle indicates compression of the neurovascular structures in the antecubital fossa by the distal end of the upper fragment. Failure of the patient actively to flex and extend the fingers is frequently the first intimation of neurovascular impairment. These signs are warnings of the most serious complication in the treatment of fractures about the elbow—namely a Volkmann's ischemic paralysis. The recognition that the radial pulse is impaired is an indication that a further attempt at reduction should be made or that the limb be suspended—as by either of these

Slight over correction was done to allow for any future downward growth of the lateral aspect of the lower end of the humerus.

methods the pressure upon the neurovascular structures may be relieved.

A roentgenographic examination should be made after the elbow has been immobilized in plaster. It is quite often difficult to visualize the outline of the fragments in the anteroposterior plane with the elbow in flexion when the roentgenograms are taken through four thicknesses of plaster splints (Fig 3 c). Nevertheless repeated roentgenograms should be made until the fragments can be visualized to ascertain the presence of mesial or lateral displacement.

After the splints have been applied, the wrist is suspended with a sling from the patient's neck. At the end of 2 weeks the splints are removed and the forearm can be placed in a sling with the elbow at a right angle. To hasten function the patient is instructed to grasp his wrist with his other hand and with this support actively flex and extend the elbow several times each hour. After another 2 weeks the sling is discarded.

Passive motion is believed to be harmful and should never be practised; active movements not only exercise the muscles but allow the patient to gauge the amount of movement that is permissible for the movements are gauged by pain.

2. *Adhesive dressing followed by early mobilization.* In 1924 I expressed a preference for the fixation of the injured elbow by means of a non-constricting adhesive plaster dressing in the posi-

Note the extraordinary reparative process resulting in a satisfactory restoration of the contour of the humerus with an excellent functional recovery.

Fig 21 O T, aged 9 years a, August 16, 1936, supracondylar fracture extending into mesial epiphysis with slight posterior and inward displacement of distal fragment b, August 21, 1936, persistent displacement of distal fragment c, December 9, 1936, lateral view shows a subperiosteal deposition of callus, while the anterior view shows the varus deformity because of failure to correct the mesial displacement and probable impairment of the mesial epiphysis d, June 12, 1937, marked gun-stock deformity

Cognizance should be taken of the reparative powers of the child under proper supervision, especially in view of the satisfactory end-results obtained with various types of supracondylar fractures treated by the closed method

ANTERIOR DISPLACEMENT OF DISTAL FRAGMENT

The lower fragment was displaced forward in 14 of the 330 supracondylar fractures (4 per cent). Eight of these had no mesial or lateral displacement, in 1 the lower fragment was displaced inward and in 5 rotated outward. Two of these fractures extended into the mesial epiphyses. In 3 the lower fragment was impacted, being angulated with the upper fragment in a position varying from 30 to 90 degrees. This injury, frequently termed the flexion type of supracondylar fracture, resulted from direct violence in all the cases. The usual history elicited was that the child fell on the flexed elbow.

In 13 cases the fracture was simple and 1 was compound. The compound fracture was complicated by a fracture of the skull and a compound fracture of the femur. Six of these fractures were transverse and 8 were oblique. Three of the transverse and 2 of the oblique fractures were comminuted. The varying displacements of the lower fragment, which have been referred to

previously, were accompanied by stripping of the periosteum from the anterior surface of the proximal fragment and off the posterior surface of the lower fragment. It is of interest, that there was no impairment of the neurovascular structures in any of these cases either before or after attempts at reduction. With the exception of the case of compound fracture, an effort was made in all the others to correct the displacement with the aid of the fluoroscope. In 5 cases a fair or a satisfactory reduction was obtained, in 1 (Case 7, R C) three attempts at reduction were made before a satisfactory alignment was obtained.

CASE 7 R C, 7 years old, female, was admitted to the hospital November 4, 1936, with a simple oblique supracondylar fracture in which the distal fragment was displaced completely forward. After the third attempt at reduction, the anterior fragment was replaced with only about 10 per cent lateral displacement. The elbow was immobilized at right angles in molded plaster splints for 3 weeks. By the aid of occupational therapy complete function was regained in approximately 4 months. Roentgenographic examination on April 10, 1937, 6 months later, revealed an increase in the transverse diameter of the lower end of the humerus with periosteal stripping and new bone proliferation from the laterally displaced lower fragment. This accounted for the increase in the carrying angle of 5 to 10 degrees (Fig 13 a, b, c, d, e, f, g).

Two attempts were made to replace the distal fragment in Case 10, J Z, in which some inward

Fig 20 GD 10 years old a November 1 1924 comminuted supracondylar fracture with medial displacement of the distal fragment b November 25 1924 poste

quently are applied improperly and cause constriction of the arm, which produces in turn an unnecessary amount of dependent swelling about the elbow, and necessitates frequent reapplication.

The adhesive plaster dressing properly applied has caused fewer complications and produced earlier restoration of function than plaster of Paris splints. Unless meticulous attention can be paid to the proper application of adhesive plaster so as to prevent possible constriction it is better that molded plaster splints be used.

3. *Suspension for unreduced fractures with or without compression of the neurovascular structures.* In neglected cases which are seen late it is often necessary to suspend the extremity by means of skin traction applied to the forearm, as the marked displacement and swelling may make reduction of the fracture most difficult or impossible (Fig 10). The surest way of relieving compression of the brachial vessels is to reduce the fragments. However, in a large number of the cases the suspension method has to be followed as it does ease the pressure upon the neurovascular structures even though it is not efficient in reducing the fragments of a supracondylar fracture in which there is displacement. As soon as the swelling has decreased, the suspension can then be discontinued and an attempt can be made to obtain a reduction of the fragments. Continuing the suspension without reducing the fragments results in mal union and the formation of an excessive amount of callus which may cause a persistent deformity and prolonged disability. At times extremely good results are obtained

rior displacement partially corrected. Note periosteal stripping c November 25 1924 note downward growth of outer aspect of lower end of humerus d and e October 13 1936 continued downward growth of outer aspect of lower end of the humerus with inward deviation of the axis of the forearm. as the reparative powers of children are such that even with persistent displacements, normal function and anatomical conformation will finally follow (Case 7, R Q Fig 11). This return may be delayed beyond the period of time required in cases in which satisfactory reduction has been obtained. It is evident from these statements that there is no justification in failing to attempt to obtain reduction of the fracture as reduction shortens the period of disability and obviates prolonged reparative process.

4. *The Thomas splint* was used in the treatment of four compound supracondylar fractures. It permitted ready access to the wound but otherwise it had no advantage over the overhead pulley adhesive plaster suspension of the forearm at right angles to the elbow.

5. *Skeleton traction.* The suspension of the elbow by means of the Hirschner wire through the base of the olecranon process of the ulna has been advocated by some in cases in which the fragments can not be held in position. This type of suspension may be indicated in cases of persistent posterior displacement with impending neurovascular changes. In the treatment of compound fractures the use of the Hirschner wire should be of great advantage in permitting ready access to the wound for dressing (Fig 12).

6. *Open operation.* Our experience in open operations for the reduction of a supracondylar fracture has been limited to one case and in that it was done for the excision of a loose articular fragment. The roentgenogram must not be the sole factor in determining upon open operation.

Fig 23 R P 6 years old a, September 1, 1928, complete posterior displacement of the distal fragment and forward rotation of proximal fragment Incomplete reduction and immobilization in plaster accompanied by obliteration of radial pulse and edema of the hand The forearm was suspended and the pulsation was restored b, September 28, 1928, incomplete reduction and persistent rotation forward of the proximal fragment c, November 5, 1928, incomplete reduction of the mesial displacement of the lower fragment with the formation of a new lower end of the shaft of the humerus under the stripped periosteum d and e, November 20, 1933, and May 2, 1936, the extent of the reparative process and the recession of the projecting proximal fragment are shown f, May 2, 1936, anterior view showing reparative process with slight downward growth of the outer aspect

displacement of the lower fragment persisted resulting in a permanent varus. This child was followed for 6 years (Fig. 14 a b c).

In 5 children the forward displacement of the distal fragment could not be reduced.

CASE 11. I. B. male aged 5 years was admitted to Bellevue Hospital on September 22 1924 1 hour after falling off a bench and striking his left elbow. Marked swelling and distortion were noted about the elbow. Roentgenographic examination revealed complete anterior displacement of the lower articular end of the humerus (Fig. 15 a). Two attempts were made to improve the position of the fragments by means of extension and flexion. Roentgenographic examination on October 11 1924 revealed the capitellum in its normal position in relation to the sigmoid with forward and upward displacement of the forearm capitellum and the rest of the distal fragment resting at right angles to the anterior surface of the proximal fragment (Fig. 15 b). Roentgenographic examination on December 25 1932 at the age of 13 years revealed the trochlea and capitellum epiphyses ossified with almost normal contour of the articular surface. There is also marked bony growth of the lower and particularly the outer end of the humerus with angulation of the distal end of the humerus (Fig. 15 c). The photographs were taken

September 22 1924 September 19 1925 and November 12 1932 when patient was 5 6 and 13 years old respectively. They reveal the gradual improvement in appearance of the elbow and the excellent range of mobility and almost imperceptible varus deformity (Fig. 15 d e f g).

CASE 4. P. M. male 6 years old was admitted to the hospital on June 6 1931 with a comminuted fracture of the lower end of the humerus which extended into the medial epiphysis. The lower fragment which was fractured from the distal part was approximately 1½ inches long and was rotated anteriorly and displaced above the articular surface. This could not be replaced and on June 14 it was removed. Because of the defect a pronounced inversion of the forearm resulted. The overgrowth of bone upon the lateral condyle and condylar ridge caused a premature ossification of the remainder of the inner humeral epiphysis. The varus deformity was corrected on June 11 1937 by a cuneiform osteotomy and two Lane plates were used to retain the divided bones in their corrected position. The plates were removed on August 2 1937 because of the excessive deposition of callus. With the removal of the plates the callus became absorbed. A satisfactory restoration of the bony contour and function of the elbow has resulted (Fig. 16 a b c d e f g).

CASE 6. F. G. male 7 years old was admitted to the hospital July 26 1936 fell on his left elbow sustaining a simple supracondylar fracture which extended into the

nated wound, (2) the reduction of the fracture especially if there is a protruding proximal fragment with or without stripped muscles, (3) the proper immobilization of the part, and (4) the method of combating the infection. If possible, the condition of the wound being satisfactory, a compound fracture about the elbow should be treated like a simple fracture. This is often possible when there is but a small wound and there is no protrusion of bone. In this type of case the skin can be cleaned, the edges of the wound carefully freed of contaminated tissue, and a dressing applied. The fracture is then reduced and immobilized by means of a posterior molded plaster splint.

A more serious problem arises where the proximal fragment is protruding. The emergency treatment of such cases is of importance as the limb should be splinted in the position in which it is found so that the end of the bone will not be withdrawn and carry contamination into the soft parts. *Under no circumstance should traction be made during the transportation and treatment of a patient with a compound fracture with a protruding fragment.* After the patient is under an anesthetic the first aid splints can be removed. The skin about the wound should be cleansed and the wound washed with saline solution. Scrubbing of the muscles is inadvisable lest one introduce infection into the muscular planes. Especial care must be taken in cleansing the skin edges and the devitalized muscles on the protruding bone. The fracture is reduced and the elbow immobilized. If the wound is not extensive and is comparatively clean, the part may be immobilized by means of a posterior molded plaster splint in the position of acute flexion. If the wound is extensive and there is gross contamination, it seems preferable to suspend the forearm in a position of acute flexion from an overhead pulley extension frame and treat the wound immediately by the Carrel Dakin method. The same method of suspension and irrigation with Dakin's solution should be used if infection supervenes in patients treated by immediate splinting. In all of these, free drainage must be established. The primary consideration is to preserve the limb and prevent a general sepsis. Although some effort should be made to maintain the fragments in the corrected position, this consideration should be secondary. If no infection supervenes the suspension may be discontinued in a week's time when the elbow can be immobilized by means of molded splints.

CAUSES AND TREATMENT OF DELAYED FUNCTION

A significant relationship exists between the unreduced or partially reduced supracondylar

fracture and delay in restoration of function. This protraction of the period of disability may be due to some complication of the fracture or may be the result of treatment.

1. *Malunion a. Persistent overriding of the fragments.* In such cases there is delay in functional recovery until callus has been deposited beneath the stripped periosteum and the protruding distal part of the upper fragment has been absorbed. Because of this, attempts at closed reduction should be continued to better the position of the fragments up to as late as 2 weeks. If these attempts are unsuccessful, the soft callus can be gently dismembered so that traction can be used. Skeletal traction, by means of a Kirschner wire to be inserted 1 inch below the olecranon process, is recommended. The elbow can then be suspended by means of this traction in a position of flexion with forearm pronated. Open operation at this late date may cause the deposit of a prolific amount of callus which may result in an elbow with limited function.

Excellent functional elbows have followed in cases in which overriding remained. In these cases, massage or forcible efforts are absolutely contra-indicated, but the patient can be encouraged to use the elbow freely. The limitation in motion is overcome gradually as the excessive callus is absorbed together with the recession of the distal end of the proximal fragment.

b. *Mesial displacement of the rotated lower fragment,* in such cases malunion and overgrowth of the lateral condyles result. This causes a deviation of the mesial aspect of the elbow with varus deformity. Every attempt should be made to correct the rotation and mesial slide of the distal fragment before union is completed and the elbow should always be immobilized in a position of flexion with the forearm semipronated. If a pronounced varus deformity has been established, it can, when the child has reached full growth, be corrected by means of a cuneiform osteotomy (Case 3, R. P., Fig. 23, a, b, c, d, e, f, g, h).

c. *Lateral displacement of the rotated lower fragment.* This causes an overgrowth of the mesial aspect of the elbow and an outward deviation of the forearm. This deformity is less obvious than the varus and not as apt to affect function. It should be prevented, however, by means of proper reduction and immobilization (Fig. 24).

d. *Varus or valgus deformity.* This is caused by a fracture of the diaphysis which extends through one of the epiphyseal plates and causes premature ossification and a unilaterally arrested growth of the affected side with normal growth of the opposite side. (For details see epiphyseal injuries.)

Fig. 23. An effective form of occupational therapy

developed an osteomyelitis of the fractured humerus and femur. The wounds gradually healed and the patient was finally referred to occupational therapy. For months the elbow was very resistant to treatment but gradually function returned until it was finally complete. Some atrophy of the interosceus muscles of the hand developed but there was no impairment of sensation of the skin supplied by the ulnar nerve. With massage and high frequency current the condition of the hand improved after about 2 years. When seen in April 1937 14 years after injury the patient had complete function of the elbow with no evidence of ulnar nerve impairment. The previous ulnar nerve disturbance was attributed to the pressure of a prolific amount of callus. With the absorption of the callus and the restoration of the normal contour of the humerus the signs and symptoms of ulnar injury disappeared (Fig. 18 a b c d e).

In evaluating the method of treatment in these 14 cases of forward displacement of the distal fragment it appears that the results were equally satisfactory whether complete reduction was obtained or not. There was no limitation of function in any of the 13 cases that were followed in 1. Case 13, D G, the child, against advice, left the hospital after the fracture had been reduced

and could not be traced. Three of the children, in whom the fractures were not reduced, and 5 in whom a satisfactory reduction was attained, ultimately had normal carrying angles. In 3 cases there was a varus deformity. In 2 of these two unsuccessful attempts had been made at reduction. In 1 case there was a slight valgus and in another there was an increase in carrying angle due to 10 per cent displacement of the lower fragment. This child had three attempts at reduction.

Analysis of these cases would lead one to infer that a proper supervision of the patient without attempts at reduction was as satisfactory as subjecting the patient to manipulation. This conclusion, however, I believe is not justified as the function is restored earlier if the fracture is properly reduced. The principle of allowing the distal fragment to remain displaced and heal by vicious union is basically unsound, and I believe that in all cases, an attempt should be made to obtain a satisfactory reduction, and in none should the fragments be allowed to remain out of alignment unless several unsuccessful attempts at closed reduction have been made.

EPIPHYSEAL INJURY

A separation of the lower epiphyses of the humerus as a whole which would include the centers of ossification of both the capitellum and trochlea has been referred to by some writers as a distinct entity. Our experience does not substantiate such a view. Wilson (9) has never encountered a 'true epiphyseal displacement of the lower end of the humerus. A study of our roentgenograms also failed to disclose such an injury. A separation through the epiphyseal line may be apparent at first in the roentgenogram but on further study it has been found that invariably the fracture line extends across the diaphysis

Fig. 26. A C, 5 years old. a August 17 1932 posterior displacement of the distal fragment and anterior rotation of the proximal. b September 12 1932 23 days later showing persistent forward rotation of the proximal fragment. c The posterior displacement corrected approximately 80 per cent. The forearm was suspended on the twenty-eighth day. d November 12 1932 note new shaft under the stripped periosteum. e The mesial displacement of the distal fragment was corrected by suspension.

at reduction was made 2 days later, which improved the position of the fragments. There was no evidence of circulatory disturbance when the boy was discharged to the Out Patient Department at the end of 15 days. On the twenty-eighth day he was readmitted to the hospital with a limitation of extension and flexion of his fingers. The roentgenogram disclosed that the upper fragment was displaced forward and inward. The limb was therefore suspended by the forearm with the elbow flexed at a right angle. Two weeks later there was slight improvement in the mobility of the hand. However, there was definite evidence of a Volkmann's paralysis. The patient was subsequently treated by means of traction of the fingers in a banjo splint, and later with plaster splints, his wrist in flexion and his fingers in extension, this was followed by gradual extension of the wrist. Function of the elbow was slow in returning, but finally at the end of 4 years full function was obtained. However, full extension at the wrist joint remained impaired (Figure 26, a b c d e).

This case is cited to call attention to an unusually late form of ischemic paralysis. It is more than probable that the circulatory changes due to the displacement of the fragments had begun before the patient's discharge from the hospital. The onset was slow and insidious but progressive, and consequently the onset of the paralysis was overlooked until it had fully developed.

It is believed that suspension of the limb prevented the onset of an ischemia in 7 of the cases though the fragments were not completely reduced and vicious union resulted in prolonged disabilities. Proper reduction and immobilization should have precluded these sequelæ.

The treatment of Volkmann's ischemic paralysis requires particular care and patience on the part of the attendant, because it is difficult to overcome the contracture and to prevent and treat trophic ulcers.

CONCLUSIONS

An analysis has been made of 330 cases of supracondylar fracture treated on the Children's Surgical Service of Bellevue Hospital during the past 18 years.

In 72 cases (22 per cent) there was no displacement of the fragments. The distal fragment was displaced posteriorly in 244 cases (74 per cent). Fourteen cases (4 per cent) are reported with a forward displacement of the lower fragment. Of the 330 fractures, in 21 (6 per cent) the line of fracture extended into the epiphyseal cartilage plate.

Of the 292 cases which were followed, 168 (58 per cent) can be said to have excellent results, 30 (10 per cent) good, 69 (24 per cent) fair, 15 (5 per cent) poor, and 10 (3 per cent) bad. These results include 52 cases (18 per cent) which are still under treatment. Many may improve in their function and will deserve a better classification.

The cause of delay in return of function was due first to a failure to obtain a satisfactory reduction of the fracture; second, to Volkmann's ischemic paralysis; third, vicious union; fourth, muscle spasm, fifth, myositis ossificans, and sixth, pressure on the ulnar or deep muscular branch of the radial nerve until the excessive callus was absorbed.

Thirteen of the 14 cases of anterior displacement of the distal fragment obtained satisfactory end-results without operative interference.

Of the 12 compound fractures, complete function was obtained in 10 cases, partial in 1, and an ankylosis in 1. Attention is directed to the danger of using traction as a first aid method in cases in which the proximal fragment protrudes through the skin lest it recedes and contaminates the deeper part of the wound.

The sooner efforts are made to reduce the displacement the more readily can the fragments be replaced and in consequence the shorter the period of disability.

To retain the reduction of the fragments so as to prevent a cubitus deformity, the part must be immobilized with the elbow flexed and the forearm semi-pronated.

It has been found that reduction can be effected even in the presence of a soft callus as late as two weeks after injury.

Failure to reduce a posterior or anterior displacement of the distal fragment in the absence of mesial or lateral displacement may result in a normal restoration of the contour of the humerus without deviation of the axis of the forearm and a complete functional recovery.

Failure to reduce the mesial or lateral displacement or rotation of the distal fragment will result in a varus or valgus deformity which the reparative powers of the child cannot change and which can be corrected only by means of a cuneiform osteotomy.

Failure to replace the lower fragment prolongs unnecessarily the period required for the return of function, because of the time it takes for the formation of a new shaft within the stripped periosteal tube.

The anteriorly displaced upper fragment pressing upon the neurovascular structures in the tense antecubital fossa is the dominant factor in the production of Volkmann's ischemic paralysis. Suspension of the forearm averted the development of this complication in 8 cases.

The line of fracture may extend through the epiphyseal cartilage plate of one of the epiphyses and cause a premature ossification in that epiphysis, resulting in a unilateral arrest of growth,

2 *Muscle spasm delays functional recovery* Although this complication occurs most frequently in fractures that have not been completely reduced it may also occur after satisfactory reduction if forceful efforts or kneading massage is used (in attempts to increase the range of mobility of the elbow). In this respect too strenuous condemnation of manipulative procedures cannot be urged, whether with or without an anesthesia. Through these procedures the injured muscles are further traumatized and though the range of mobility may be increased at first, this manipulative procedure is always followed by a greater limitation of motion and more apprehension on the part of the child. I believe that muscle spasm should never be treated by any form of physiotherapy, but that the patient should be encouraged in the use of the elbow by treating him with some form of occupational therapy (Fig 25).

3 *Myositis ossificans traumatica* This complication has not been encountered on the Children's Surgical Service since the first group of cases were reported. It is believed that myositis ossificans traumatica results from repeated trauma to already injured muscles and periosteum. We believe, therefore, that the presence of the 7 cases of this complication, in the former group, was the result of massage and passive motion, which we then used, for when the presence of myositis ossificans was recognized and the physiotherapy had been discontinued, all evidence of this complication disappeared within a few months. Dean Lewis believes that "periosteal stripping plays an important rôle in the development of periosteal callus and ossifying myositis." But in this series we have not observed this complication unless there was added trauma, which had been caused by some form of physiotherapy.

4 *Volkman's ischemic paralysis* The posteriorly displaced lower fragment carrying the forearm with it causes the neurovascular structures, which are intimately bound to the latter, to impinge upon the distal sharp end of the anteriorly displaced proximal fragment. Nine cases of impending Volkman's paralysis were recognized in this series because of absence or impairment of the radial pulse. By recognizing this premonitory sign, further damage was averted, either by means of obtaining a satisfactory reduction of the fracture and immobilization of the part or through suspension of the forearm. Both of these methods relieve the pressure on the neurovascular structures by the proximal fragment.

Ischemic paralysis has been reported by some to be due to pressure of a hematoma within the

antecubital fossa even though there be no displacement of the fragments. Others have ascribed it to constrictive dressings. Neither of these causes have been encountered in this series.

Numbness, cyanosis, swelling, inability to extend the fingers without causing pain, and impairment of sensation indicates that the disease has progressed. These symptoms are actual signs of ischemic paralysis and therefore should not be awaited before measures of relief are instituted. The slightest impairment of the pulsation of the radial artery is the warning that danger is impending.

The cases in which this complication was threatened followed unsuccessful attempts at reduction in which the arm was immobilized in acute flexion. In 8 instances the radial pulse became imperceptible and the fingers began to swell, thereupon the dressings were removed. In 6 of these the forearms were suspended and in 2 the displacement was corrected by further manipulation after which the elbow was immobilized in flexion by means of plaster splints. In all of these 8 cases the pulsation of the radial artery immediately returned. In each the roentgenogram showed a forward displacement of the proximal fragment. The suspension of the limb in 6 cases did not improve the position of the fragments but did immediately relieve the pressure upon the neurovascular structures. With the exception of 1 case (Case 6), 5 were treated by suspension until union was firm. In this case a reduction to the extent of 80 per cent was obtained through manipulation as late as the eighth day and the elbow was then immobilized in flexion by means of plaster splints. In all 8 cases complete function was regained and none showed further signs of ischemia. One child now has a normal carrying angle, 1 a valgus and 6 varus deformities varying from 5 to 10 degrees. The change in the carrying angle resulted from a failure to correct the mesial or lateral displacement of the distal fragment.

Case 5 (A-C) is of sufficient interest to report in detail as the circulatory disturbance was of an insidious nature, inasmuch as the condition was not recognized until 2 months following discharge from the hospital.

CASE 5. A-C. 6 years old fell on his outstretched hand on August 16, 1932. There was the typical clinical picture and roentgenographic findings of a supracondylar fracture with a complete posterior and lateral displacement of the distal fragment. An attempt was made to reduce the fracture following which the elbow was immobilized in acute flexion. At this time there was no evidence of impairment of circulation. The x-ray film however revealed an unsatisfactory position of the fragments. Another attempt

Fig 1 Procaine

not a few cases, when metycaine was used, anesthesia was complete when the injection was completed. The regularity with which anesthesia was rapidly established in 667 cases emphasized the advantage which metycaine has as a local anesthetic agent for sacral plexus block. There is a definite time-saving factor for the surgeon when metycaine is used because anesthesia is established quickly, and a benefit to the patient because prolonged anesthesia makes the postoperative period more comfortable.

PREPARATION OF THE SOLUTION

One 5 cubic centimeter ampul of 20 per cent solution of metycaine is added to 95 cubic centimeters of physiologic solution of sodium chloride, the temperature of which is maintained at about 37.5 degrees C. The contents of another ampul containing 1 cubic centimeter of 1:2600 solution of epinephrine is added to the solution of metycaine and sodium chloride. Under certain circumstances, such as marked hypertension or thyrotoxicosis, or in the presence of some cardiac condition such as angina pectoris, the epinephrine is omitted.

Briefly, 25 to 30 cubic centimeters of 1 per cent metycaine is injected into the caudal canal, and 15 cubic centimeters of the same solution is injected transsacally on each side, in the second, third, and fourth foramina, 10, 3, and 2 cubic centimeters, respectively, being used. The total

HCl

Hydrochloride of gamma-(2-methyl piperidino)-propyl benzoate

Fig 2 Metycaine

amount of 1 per cent solution of metycaine used is usually 60 cubic centimeters.

SUMMARY

Metycaine may be substituted for procaine as a local anesthetic agent with certain advantages. It produces anesthesia in equivalent dosages more rapidly than does procaine and anesthesia is more enduring than when procaine is used. Clinically it is no more toxic than procaine as a regional anesthetic. Metycaine, which is a fourth as toxic as cocaine, may be used instead of cocaine for topical anesthesia with satisfactory results. It may be of interest to some anesthetists who are sensitive to contact with procaine that they may try metycaine as an alternative local anesthetic agent. I know of a physician who had dermatitis from procaine but who is able to use metycaine with impunity.

which is followed by a deformity due to the normal growth of the unaffected epiphysis.

Open reduction does not appear to be justified in supracondylar fractures in view of the uniformly good results obtained by various procedures for closed reduction.

The author wishes to express his appreciation to Dr Fenwick Beckman, surgeon in charge of the Children's Surgical Service for permission to report on these cases and for his many helpful suggestions.

THE USE OF METYCAINE FOR PRODUCING BLOCK ANESTHESIA OF THE SACRAL NERVES

EDWARD B. TUOHY, M.D., M.S. (Ages), Rochester, Minnesota

THE technique and indications for producing anesthesia of the sacral nerves have been described elsewhere (1). It is not the purpose of this paper to offer any changes in fundamental procedure but to suggest that a new anesthetic agent, metycaine (2) may be used to advantage instead of procaine.

Chemically, procaine and metycaine (2) are related in that they are both derivatives of cocaine, but the addition of substitution products causes the two agents to have different chemical and clinical properties (Figs. 1 and 2). Metycaine is both a local and a topical anesthetic agent, whereas procaine does not possess any local anesthetic action on topical application. Metycaine also possesses anesthetic properties which are not present in procaine.

Mecke and McCreary, who have compared the anesthetic potency of procaine and metycaine by means of intradermal injection, found that anesthesia which was induced with 0.0625 per cent of procaine without epinephrine, lasted 5 minutes, whereas anesthesia which was induced with an equal amount of 0.0625 per cent of metycaine lasted 14 minutes. Several other workers (4, 5) have confirmed these observations that anesthesia which is induced with metycaine is more enduring than that which is induced with procaine. The toxicity of these agents has been studied by means

of injecting them intravenously into animals. When metycaine is injected intravenously, it is found to be two or three times more toxic than procaine but, clinically, Rose and others have found that metycaine is no more toxic than procaine. Further, in comparison with cocaine, metycaine is about a fourth as toxic as cocaine and possesses considerable anesthetic power. A 2 to 4 per cent solution of metycaine is the usual strength for topical anesthesia. I have used metycaine for infiltration and block anesthesia with satisfactory results and have not noticed any evidence that metycaine was more toxic than procaine.

As an agent to produce anesthesia of an individual nerve or of several nerves such as those of the brachial or sacral plexus, metycaine has been found to produce quicker anesthesia in equivalent doses and the anesthesia lasts about 50 per cent longer than that produced with procaine. Previously 1 per cent procaine with epinephrine was the agent usually used for caudal transsacral anesthesia. With this agent and concentration, it was expected that anesthesia would be established within 12 to 15 minutes after completion of the injection and that the duration would vary from 1 to 2 hours. When 1 per cent metycaine with epinephrine is used, anesthesia usually is complete within 6 to 8 minutes after the injection has been completed and endures for 2 hours or longer. In

When the baby leaves the uterus, the uterus contracts and is so reduced in size that the placenta cannot possibly remain attached; it is therefore cast off from the uterine wall. It is wrong to suppose that only a part of the placenta begins to separate and that it separates gradually. The entire placenta separates immediately, as soon as the baby leaves the uterine cavity.

The only exception to the immediate separation of the placenta is in the pathologically adherent placenta accreta, which fortunately occurs so rarely. In these 11,000 cases there were no cases of placenta accreta. The usual so called adherent placentas are in reality only retained placentas. The uterus in those cases is so firmly contracted down on the placenta that it gives the impression that the placenta is adherent, but in reality it is only retained. The parts of the secundis that do remain attached to the uterus are parts of the membranes around the periphery of the placenta. There is no special mechanism by which the membranes become detached from the uterus, they are dragged away from the uterus when the placenta is delivered.

The management of the third stage is as follows: When the baby is delivered the nurse follows down the uterus through the abdominal wall and holds it firmly. The baby is cared for by tying the cord, placing an identification tag on it, and treating the eyes, all of which takes about 3 minutes. If there is a probability of the rubber gloves having been contaminated during the delivery they are changed. An artery clamp is placed on the cord close to the vulva. A vaginal examination is made with two fingers of the right hand, while the left hand holds the artery clamp that is on the cord. The nurse makes pressure on the uterus forcing the placenta down and out of the uterus, aided by a little traction on the cord by the left hand. The placenta is then guided out or lifted out of the vagina by the right hand (Fig 1). The membranes are dragged out after the placenta, to prevent tearing, artery clamps are used to grasp the membranes as they appear at the vulva. One ampul of pituitrin is injected and an ergot preparation is given either by mouth or intramuscularly.

The placenta is nearly always delivered by this procedure in about 3 minutes after the delivery of the baby. If progress is not made it may be that pressure is not exerted in the right direction. The pressure on the uterus should be so placed that the force will be exerted over the placenta and directed toward the outlet. The vaginal fingers determine whether the pressure on the uterus is in the right direction, the procedure is

Fig 1 The delivery of the placenta. Vaginal examination is made with two fingers of the right hand, to determine whether the placenta is ready for delivery. The left hand makes a little traction on the cord, while the nurse pushes down on the uterus from above and the placenta is expelled from the uterus. It is lifted out of the vagina by the right hand.

then continued until the delivery of the placenta is accomplished.

A bimanual examination is then made to assure that the uterus is well contracted and to detect lacerations. The placenta is examined by inspecting both surfaces, the membranes and the blood vessels. No elaborate methods are necessary to verify that parts are not missing.

When the fingers of the right hand enter the vagina and cervix, the placenta is encountered either in the Duncan or the Schultz position or in different variations of these presentations. The placenta is found to be separated, lying loose in the uterus, and partly protruding from the cervix into the vagina. Often the membranes at the rim of the placenta will be found attached to the uterine wall. These attached membranes frequently hold back the placenta from being expelled. The examining fingers in that case reach up in the lower uterine segment and detach the membranes from the uterine wall, permitting the placenta to come down. This does not mean that

MANAGEMENT OF THE THIRD AND FOURTH STAGES OF LABOR

Based on Eleven Thousand Deliveries

MORRIS LEFF, M.D., New York, New York

CONSIDERABLE uncertainty and disagreement as to the proper management of the third stage of labor still persists. Ever since recorded time, numerous methods have been advocated and used with variable success or failure. All agree that the third stage requires proper management but differ as to what constitutes the correct method.

The observations to be presented here are based on 11,000 cases delivered at our hospital of these 7,500 were my own private cases delivered by me, and 3,500 cases were delivered by other doctors, and directly or indirectly supervised by me.

The third stage of labor embraces the period from the birth of the child to the delivery of the placenta. After the delivery of the placenta the puerperium is assumed to begin. However after the delivery of the placenta there is a very important and dangerous interval that lasts from a few minutes to several hours which requires the serious attention of the obstetrician. That interval between the delivery of the placenta and the time that the patient is safely in bed without any more danger of hemorrhage should be designated as the fourth stage. After this stage, then the puerperium can be considered to begin.

The third stage of labor consists of two phases—the first, the separation of the placenta and the second, the delivery of the placenta. The separation of the placenta is a normal physiological process which is accomplished entirely by the contraction of the uterus and the reduction in its size as soon as the baby is born while the second phase, the delivery of the placenta, is as a rule not accomplished by the natural forces but must have the assistance of the obstetrician.

In primitive people, if the woman delivered in the erect posture the cord and the placenta would be dragged out with the baby or could come out by the force of gravity. In civilized times with the woman delivering in the supine position the natural forces cause the complete separation of the placenta, but as a rule these forces do not

complete the process of expulsion of the placenta. The delivery of the placenta has to be aided artificially. It is only occasionally that powerful uterine contractions force the placenta out of the vagina. We must recognize as a fundamental fact, that in humans, nature does not provide for the expulsion of the placenta spontaneously and that it is therefore necessary for the obstetrician to aid in its delivery, just as definitely as it is necessary to tie and cut the umbilical cord. Since the obstetrician must aid in the delivery of the placenta it is essential to know exactly the mechanism of the third stage. The mechanism can be ascertained in each case only by vaginal examination, as indicated in my paper, 'Vaginal Examination in the Third Stage of Labor as a Guide to Its Management' (December, 1929).

The generally considered signs of separation of the placenta are of no value. Placing a clamp on the cord at the vagina and watching its descent does not indicate that the placenta is separating, because by the time the clamp is placed on the cord the placenta is already separated. Pushing up on the uterus through the abdomen and noticing that the cord rises up with it, is no indication that the placenta has not separated because the placenta will accompany the uterus although it is separated and is simply held by the lower uterine segment and cervix. The globular or flattened shape of the uterus is no indication that the placenta has or has not separated. There are no external signs by which we can know that the placenta has separated and is ready for delivery. Vaginal examination therefore must be done. I consider it indispensable in the management of the third stage of labor.

Vaginal examination is done by me in all stages of labor. Introducing the sterile gloved hand in the vagina does not cause infection. It gives definite and positive information as to the conditions present and eliminates guesswork and mistakes. I am convinced that vaginal examination under aseptic precautions does not produce infection. In the 11,000 deliveries we have not had a single case of puerperal sepsis and the morbidity in general was exceedingly low.

When the baby leaves the uterus, the uterus contracts and is so reduced in size that the placenta cannot possibly remain attached, it is therefore cast off from the uterine wall. It is wrong to suppose that only a part of the placenta begins to separate and that it separates gradually. The entire placenta separates immediately, as soon as the baby leaves the uterine cavity.

The only exception to the immediate separation of the placenta is in the pathologically adherent placenta accreta, which fortunately occurs so rarely. In these 11,000 cases there were no cases of placenta accreta. The usual so called adherent placentas are in reality only retained placentas. The uterus in those cases is so firmly contracted down on the placenta that it gives the impression that the placenta is adherent, but in reality it is only retained. The parts of the secundis that do remain attached to the uterus are parts of the membranes around the periphery of the placenta. There is no special mechanism by which the membranes become detached from the uterus, they are dragged away from the uterus when the placenta is delivered.

The management of the third stage is as follows. When the baby is delivered the nurse follows down the uterus through the abdominal wall and holds it firmly. The baby is cared for by tying the cord, placing an identification tag on it, and treating the eyes, all of which takes about 3 minutes. If there is a probability of the rubber gloves having been contaminated during the delivery they are changed. An artery clamp is placed on the cord close to the vulva. A vaginal examination is made with two fingers of the right hand, while the left hand holds the artery clamp that is on the cord. The nurse makes pressure on the uterus forcing the placenta down and out of the uterus, aided by a little traction on the cord by the left hand. The placenta is then guided out or lifted out of the vagina by the right hand (Fig 1). The membranes are dragged out after the placenta, to prevent tearing, artery clamps are used to grasp the membranes as they appear at the vulva. One ampul of pituitrin is injected and an ergot preparation is given either by mouth or intramuscularly.

The placenta is nearly always delivered by this procedure in about 3 minutes after the delivery of the baby. If progress is not made it may be that pressure is not exerted in the right direction. The pressure on the uterus should be so placed that the force will be exerted over the placenta and directed toward the outlet. The vaginal fingers determine whether the pressure on the uterus is in the right direction, the procedure is

Fig 1 The delivery of the placenta. Vaginal examination is made with two fingers of the right hand, to determine whether the placenta is ready for delivery. The left hand makes a little traction on the cord, while the nurse pushes down on the uterus from above and the placenta is expelled from the uterus. It is lifted out of the vagina by the right hand.

then continued until the delivery of the placenta is accomplished.

A bimanual examination is then made to assure that the uterus is well contracted and to detect lacerations. The placenta is examined by inspecting both surfaces, the membranes and the blood vessels. No elaborate methods are necessary to verify that parts are not missing.

When the fingers of the right hand enter the vagina and cervix, the placenta is encountered either in the Duncan or the Schultze position or in different variations of these presentations. The placenta is found to be separated, lying loose in the uterus, and partly protruding from the cervix into the vagina. Often the membranes at the rim of the placenta will be found attached to the uterine wall. These attached membranes frequently hold back the placenta from being expelled. The examining fingers in that case reach up in the lower uterine segment and detach the membranes from the uterine wall, permitting the placenta to come down. This does not mean that

Fig. 2 The placenta presenting in the Schultze manner. The examining finger pokes a hole in the presenting part of the placenta permitting the accumulated blood to drain out and the placenta to collapse and to be more easily expressed.

the placenta is not separated—only that the membranes at the rim of the placenta remain adherent. They would remain attached no matter how long one would wait as there is no mechanism for the membranes becoming detached except by being dragged away when the placenta is delivered.

When the fingers encounter the placenta presenting in the Schultze manner there is usually no visible bleeding as the placenta obstructs the entire cervical outlet but invariably there is bleeding in back of the placenta. This blood forms the so called retroplacental hematoma which is the result of the placenta staying in the uterus and which keeps the uterus distended and increases the bleeding. Before an attempt is made to express the placenta in that case the accumulated blood should be permitted to drain out. This is done by poking a hole in the presenting part of the placenta with the examining finger permitting the blood to run out and uterus to contract (Fig. 2). The placenta then folds up on itself and permits the uterus to contract further and the placenta is then easily expelled. This procedure also avoids the splash of blood which otherwise accompanies the delivery of the placenta. To press on a uterus which is distended while the cervix is dilated as it is when the placenta presents by the Schultze method is to invite the danger of inversion of the uterus. By the above maneuver this is prevented. We have not had any cases of inversion of the uterus in the entire series.

Occasionally, as the baby is delivered the cervix closes down immediately. On vaginal examination the cervix will be found to be entirely closed or only one or two fingers dilated under these circumstances the placenta cannot be delivered although it is separated. When there is no dilatation nothing can be done but to wait for the uterus to relax and for the cervix to open up. These are the cases in which the placenta may be retained and may require anesthesia and manual removal. If a piece of placenta protrudes into the cervical canal it will act as a wedge and dilate the cervix. When the cervix is about two fingers dilated then the examining fingers are held in the cervix and aid in the dilatation of the cervix they are kept there until the cervix is sufficiently dilated for the placenta to be expressed. When the cervix is closed or partially closed pressure is not made on the uterus, but it is rather allowed to relax for with the relaxation of the uterus the cervix also relaxes and dilates. When the cervix is sufficiently dilated then pressure is made on the uterus and the placenta is expressed. It is the occasional closing down of the cervix which prevents us from delivering every placenta immediately. But when the cervix is open all placentas are and should be delivered promptly without delay.

If the placenta is retained in the uterus only one hour is allowed to elapse before manual removal is done. There is nothing gained by waiting any longer. The anesthesia relaxes the uterus and cervix and the placenta can then be removed. The membranes at the margin of the placenta may be found adherent but the placenta itself is separated. It is not advisable to wait a longer time for the removal of the placenta as persistent bleeding is bound to occur which may be slow and small in quantity but in time adds up to a considerable amount. This blood loss is unnecessary and may become dangerous. The mental strain on the patient and the doctor in waiting must also be considered. Furthermore we know that in about 3 hours the uterine cavity becomes invaded with micro-organisms and if we delay the removal of the placenta it would involve manipulation in an infected area instead of in a comparatively clean uterus. By delivering the placenta promptly as has been indicated the cervix does not get a chance to close down on the placenta so that fewer cases of retained placenta occur which require manual removal.

The Mojon Gabaston method of inducing the separation of the placenta has recently been resurrected. It is mentioned here only to be condemned. Fortunately, in the cases described in

Fig 3 Fourth stage of labor Bimanual compression of the uterus to control hemorrhage Two fingers of the right hand are inserted in the anterior fornix, they push the uterus up against the abdominal hand, thus causing compression of the uterus

which the method was used, the placentas undoubtedly had already been separated Had it really been used in adherent placentas the fluid injected would have penetrated the uterine wall and caused tearing of the uterus

When the baby is delivered and there is a gush of blood and the bleeding continues, immediate attention should be given to the placenta The cord is promptly clamped and cut and the baby is handed to the nurse The placenta is immediately delivered and the bleeding controlled Any and all bleeding before the placenta is delivered is to be considered unnecessary, and is an indication that the placenta should be delivered without the least delay

The natural process by which bleeding from the uterus is controlled is by the retraction and contraction of the uterus Anything which helps contraction of the uterus will help control the bleeding, and anything which interferes with the contraction of the uterus will increase the bleeding Therefore a uterus which is exhausted from a prolonged first and second stage is more apt to bleed Anesthesia definitely interferes with the contraction of the uterus, consequently the deeper the anesthesia the longer will the uterus remain relaxed and induce bleeding It is therefore advisable to use as little anesthesia as possible, and to discontinue it promptly as soon as the baby is delivered For the same reason a mini-

Fig 4 Fourth stage of labor Bimanual compression of the uterus with closure of the cervix Two fingers of the right hand are inserted into the lateral fornices They compress the cervix, closing it, and at the same time they lift the uterus up toward the abdominal hand, producing compression of the uterus

um amount of anesthesia should be used during the repair of the perineum

Pituitrin as a rule is given after the placenta is delivered, lately ergotrate is given instead, or with it However, when the patient had been deeply anesthetized, the pituitrin is given immediately as the baby is born, even before the placenta is delivered, so as to counteract the relaxing effect of the anesthesia sooner

The fourth stage now begins, which is concerned primarily with the control of bleeding and secondarily with the repair of lacerations All repairs are done after the placenta is delivered

With the hand on the abdomen the nurse continues to hold the uterus after the placenta is delivered and makes pressure on it Two fingers of the right hand are inserted in the vagina in the anterior fornix, and pressure is made against the anterior wall of the uterus, the fingers push the uterus up against the hand on the abdomen (Fig 3) Or the fingers pass on each side of the cervix in the lateral fornices and compress the cervix

from side to side closing the cervix and at the same time pushing the uterus upward (Fig 4). Thus bimanual compression of the uterus is attained. Without the fingers in the vagina the abdominal hand only pushes the uterus down in the vagina in an empty cavity but does not compress the uterus. The vaginal fingers are held against the uterus, and pressure from above is continued until the uterus is felt to be well contracted. This method of vaginal examination and bimanual compression of the uterus is done practically as a routine in all deliveries. Before the fingers are removed all clots are removed from the cervix and vagina and the cervix and vagina are palpated to determine the extent of any and all lacerations.

When the uterus is very much relaxed and the bleeding is considerable the entire hand is inserted in the vagina and the fingers gather up the walls of the cervix and compress it from all sides, at the same time the uterus is pushed upward against the abdominal hand until compression of the uterus is attained (DeLee Fig 714). At frequent intervals the cervix is allowed to open up so that the accumulated blood can escape and the clots can be expressed. The uterus cannot contract properly while there are clots in it. The oxytocics are repeated if necessary. Contraction of the uterus and control of bleeding must be attained.

Bleeding below the clitoris should be promptly observed and must receive immediate attention as it may be very profuse. Pressure controls it temporarily until the tear is sutured.

When a vaginal hematoma is detected in the process of forming it should be incised. The vessels can then retract and the bleeding will cease or the bleeding area should be sutured. The vagina should be packed with iodoform gauze whether the hematoma is incised or not so as to produce pressure and thereby prevent its extension. When the patient complains of severe pain in the vagina radiating toward the rectum vaginal hematoma should be suspected.

Packing the uterus to control bleeding is not resorted to as it is not considered desirable. Although to pack a uterus is not a difficult procedure to pack it perfectly and completely is not simple. With whatever quantity of gauze the uterus is packed the uterus may still further relax as it is not a solid structure and the bleeding may not be controlled. On removal of the packing hemorrhage may recommence. It is unphysiological to pack the uterus as the means of controlling the hemorrhage is for the uterine muscle fibers to retract and contract and eliminate

the sinuses whereas if the uterus is packed the sinuses remain distended.

Packing the vagina is done very frequently. Its main object is to fill the empty cavity of the vagina so that pressure can be made on the uterus from above against something solid instead of an empty space. It also aids in controlling bleeding from the vagina or cervix. When the bleeding is more or less controlled by bimanual compression as has been described, and the uterus still has a tendency to relax, then the vagina is packed as a precaution against further bleeding. Packing is not done while the bleeding is still continuing. The bleeding must first be controlled by bimanual compression otherwise clots will be retained in the cervix and the uterus and induce more bleeding. Iodoform gauze (5 per cent) is used for packing. The gauze is 8 inches wide folded to one inch and ten yards long. It is put up in glass jars ready for use. The tubular packer (DeLee Fig 790) simplifies the procedure greatly. The packer used is $1\frac{1}{16}$ of an inch in diameter, and has two prongs. It should vary in diameter according to the width of the gauze used.

Even in placenta previa it is not considered advisable to pack the uterus after delivery as the packing will distend the sinuses and maintain the bleeding. Packing the vagina compresses the cervix and with pressure from above contraction of the uterus and cervix is more likely to be attained.

The patient is kept in the delivery room until all bleeding is controlled and the uterus is well contracted. Frequently the patient is in bed 15 minutes after the birth of the child, and at other times she remains on the delivery table for an hour or longer.

The repair of the perineum is done after the placenta is delivered and the bleeding is controlled. For the technique of the repair of the perineum the reader is referred to the standard text books on the subject. DeLee's excellent illustrations describe all forms of repair. As little anesthesia should be used as is possible so as not to induce relaxation of the uterus. Cervical lacerations are not as a rule sutured as most tears which appear extensive shrink to insignificance when the cervix contracts.

In repairing second degree lacerations or episiotomies I find it unnecessary to suture the different structures in separate layers. The superficial and deep structures are sutured together with the same stitch. I find that if the deep layers are sutured separately the suture and the knot in the deep layer collect the lochia and interfere with the healing. Whereas when a through suture is

used for the superficial and deep layers, primary union is more apt to occur. The suturing can thereby be done much more quickly and be completed before the patient reacts from the previous anesthetic, without the need of prolonging it, or it may be done under first stage anesthesia. This does not apply to third degree lacerations, which require delicate repair of the different structures. By resorting to proper episiotomies third degree lacerations can usually be avoided. While the repair is being done the uterus should be held firmly and not allowed to relax. If it tends to relax, the repair should be interrupted and attention given to the uterus.

When the patient is placed in bed she still needs watching, as the uterus is still liable to relax. Abdominal binders are used postpartum, as the patients prefer them, but the binder is not put on for several hours after the patient has been in bed, so that the nurse can continue to feel the uterus. In watching the uterus the nurse must know what constitutes a firmly contracted uterus, otherwise an inexperienced nurse may be holding a uterus which may be filling up with blood and be under the impression that it is well contracted.

If the uterus relaxes when the patient is in bed, all clots must be expressed. If in doubt, vaginal examination is done again and the clots are removed from the cervix and vagina. When the vagina has been packed and it is found that serum runs out through the packing, it is a sign that blood clots are accumulating in back of the packing. If the uterus rises up or fresh blood is expressed or there are other signs of bleeding or even a suspicion of bleeding, the packing is removed, the clots are expressed, and the vagina is repacked. When the patient, after being in bed, continues to complain of cramps which are more severe than the usual afterpains they may be due to blood clots in the uterus. The removal of the packing, or vaginal examination or repacking can be done in bed if necessary. Sterile towels are used to drape the area, and with sterile gloves and the tubular packer, the vagina is repacked with iodoform gauze.

It is evident from this description that we do not practise watchful waiting for bleeding in the hope that the bleeding will cease by itself. Active measures to control bleeding must be taken promptly to avoid unnecessary or excess loss of blood.

In our entire series there were no deaths directly attributable to hemorrhage. The deaths that did occur from hemorrhage were in cases of placenta

prævia, and in one case of a bleeder in which the blood failed to clot and transfusion was of no avail.

It should be evident that the technique described and advocated ought to be effective in causing contraction and compression of the uterus and the control of bleeding. The great objection raised would be against doing vaginal examination, for fear of infection. The antagonism against vaginal examinations has reached the stage of a phobia or a superstition with many obstetricians. Conditions are overlooked, diagnoses are guessed at, and patients are neglected because of the unwarranted fear of making vaginal examinations. By the method described of managing the third and fourth stages, the blood loss is greatly reduced, our patients rarely require blood transfusions, and they make a better postpartum recovery. All the vaginal examinations are, naturally, done under aseptic precautions. There are absolutely no ill effects resulting from them. The morbidity is very low with no mortality from infection.

I consider vaginal examination in all stages of labor and the active treatment in the prevention and control of hemorrhage absolutely essential for proper obstetric practice.

SUMMARY

The term, third stage of labor, should be limited to the delivery of the placenta. The interval thereafter, between the delivery of the placenta and the time the patient is ready for bed, is designated as the fourth stage. It concerns itself primarily with the control of hemorrhage.

The placenta separates as soon as the baby is born. Vaginal examination is done and the placenta is promptly expressed. No ill effects result from vaginal examination.

Vaginal examination and bimanual compression of the uterus are done to control hemorrhage.

The vagina is frequently packed with iodoform gauze, but not the uterus.

The technique used for the third and fourth stages of labor, which gives very satisfactory results, is described.

FAT NECROSIS—GRANULOMA OF THE BREAST

S F LIVINGSTON, M D, and M LEDERER M D Brooklyn, New York

THE importance of recognizing traumatic fat necrosis of the breast lies in the fact that clinically it closely resembles carcinoma.

The clinical criteria for the diagnosis or exclusion of malignancy in the breast fall short when confronted with a tumor in a middle aged woman, who is overweight and whose breasts are fatty. Such findings as hardness of a tumor, or one that is not circumscribed, showing attachment to the skin overlying it or retraction of the nipple in most cases justifies the clinical suspicion of cancer. Yet the same findings are seen in traumatic fat necrosis.

This condition was first brought to the attention of surgeons by Lee and Adair in 1920 (4) when they reported 2 cases. In 1922 they reported 3 additional cases (5) and in 1924 (6) they collected all known cases from their own clinic and other sources. This formed a group of 20 cases from which they drew the following conclusions: 'This condition occurs as a rule in middle aged individuals. In practically every incident the woman was far beyond the normal weight. As the disease occurs in unusually adipose individuals, the breasts are unusually large. Trauma was obtained in the history of 14 or 70 per cent of the cases. The tumor is painless and in the majority of the cases is stony hard. The tumor may be adherent to the skin overlying or to the deep fascia. The nipple may show evidence of retraction (occurring in 20 per cent of their cases).

Since the report of this group a number of isolated cases have been reported. Geoffrey Keynes was the first to call the attention of British surgeons to the existence of this condition when he reported the case of fat necrosis in a woman on whom a clinical diagnosis of cancer was made with a consequent complete amputation of the breast pectoral muscles and the axillary fat. Cecil Rowntree reported a case of fat necrosis in a woman in whom a provisional diagnosis of carcinoma or tuberculosis was made and an amputation of the breast was performed. Manville reported 25 cases of fat necrosis in which a pre-operative diagnosis of malignancy was made in 29 per cent of the cases. Thus clinically it is very often difficult to diagnose the condition

excepting as in one case reported by J J Levin in which the presence of a tumor followed a definite history of trauma namely after hypodermolysis.

The surgeon must become very familiar with the gross appearance of the tumor in order to avoid mistakes. Ewing states (6) "that the tumor is usually pale dull, grayish white homogeneous, and chalky in appearance. The outline of the gross lesion in carcinoma is generally much sharper than in fat necrosis which may fade off gradually into surrounding areas. Chalky points and streaks of fatty epithelium lying in firm translucent connective tissue are characteristic of infiltrating carcinoma. The same whitish points are present in necrotic or inflamed fat tissue but they are generally much broader and more irregular. Occasionally, one finds a whole fat lobule as large as a bean chalky and opaque from the proliferation of fat cells in inflamed fat tissue. Carcinomatous nodules in the breast are nearly always single, whereas traumatized fat is often very irregularly distributed and cicatrization appears in multiple points.

The microscopic section furnishes a correct interpretation at once from the presence of much cellular overgrowth, fibroblasts mingled with lymphocytes, empty spaces once filled with fluid fat (oil cysts) and many phagocytic giant cells and wide areas of proliferating fat cells.

Keynes in his report states "fat necrosis of the breast is not a lesion of the mammary gland proper, but the fat which overlies or infiltrates the mammary gland in later life. Grossly the appearance of chalky whiteness of the necrosed areas of fat resembles fat necrosis seen in acute pancreatitis. Microscopically the presence of embryonic fat cells and multinucleated giant cells, stamps the tissue as necrotic fat. Two illustrative case reports of this condition are offered.

The first case described is particularly instructive because although it fulfilled all clinical criteria for a diagnosis of malignancy, it proved to be a benign lesion. The diagnosis made pre-operatively was carcinoma and a radical amputation was performed. The second case was seen soon after the first a correct pre-operative diagnosis was made, and excision of the lesion only was done.

From the Breast Clinic, Department of Surgery and Division of Pathology, the Jewish Hospital of Brooklyn.

Fig 1 Fat pendulous breasts Retraction of right nipple

Fig 2 Intracanalicular granuloma $\times 12$

CASE 1 No 188875 A short, stout, 53 year old woman was first seen in the out-patient department of the Jewish Hospital of Brooklyn on October 11, 1934. At that time a working diagnosis was made of menopausal syndrome and obesity, for which she was treated. On February 27, 1936, she returned to the clinic complaining of a lump in the right breast of 6 months' duration. This lump had never caused any pain nor had it increased in size. Within the past month the patient had been able to express a reddish brown, and sometimes bloody, discharge from the right nipple.

Physical examination revealed a middle aged, short, and rather corpulent woman. The breasts were large, fatty, and pendulous (Fig 1). There was a mass in the outer quadrant of the right breast about 4 centimeters from the nipple which measured 3.5 by 2.5 centimeters in size. It was firm, irregular in outline, not encapsulated and felt as though it were deep in the breast tissue. The overlying skin was adherent—and when the patient leaned forward, allowing the breast to sag, there was noticeable retraction and dimpling of the skin overlying the mass. The nipple was retracted (Fig 1). There were two small lymph nodes about 1 centimeter in diameter palpable high in the axilla which felt soft. No history of trauma could be elicited from the patient. A pre-operative diagnosis of carcinoma of the breast was made. Because of the soft consistency of the tumor, an element of doubt was cast on the diagnosis.

The mass was excised with a good portion of surrounding normal breast tissue. Sectioning imparted a gritty sensation to the scalpel. The cut section was brown-yellow in color, granular and firm. Although it did not have the typical cicatricial appearance nor the chalky points or streaks, nor the Bartlett pear appearance which is characteristic of carcinoma, the clinical conception of this case

more than the unusual appearance of the cut section, made one feel that a radical operation would be the safer procedure. The remainder of the breast, pectoral muscles, and axillary contents were removed. The patient made an uneventful recovery and was discharged.

Pathological report, gross. The specimen consists of a breast and associated structures. One surface is covered by an elliptical portion of skin, 21 by 20 centimeters, including the nipple. Lateral to the nipple is a gaping aperture, 8 by 4 by 3 centimeters. The underlying adipose tissue is 6 centimeters thick and attached to the posterior surface is a portion of muscle tissue, 17 by 9 centimeters. Attached to one edge of the specimen are several, firm lymph nodes measuring up to 1.5 by 1 by 1 centimeter. Their cut surfaces are pale gray and bulge. Sections through six of these were taken for microscopic study. Corresponding in shape and size to the cavity and received separately, was a portion of firm, yellow and white tissue, 7.5 by 4 by 3 centimeters. It is composed of circumscribed areas of dense, white and gray tissue. In the cut surfaces, spaces up to 0.3 centimeter are filled with firm, brown and white tissue. In one area strands of dense white tissue in a branching arrangement are noted.

Microscopic. Large lumina of ducts and acini, filled with a cellular debris, are lined by cuboidal cells with nuclei heaped up into several rows. In places the epithelium is desquamated and in the surrounding loose and dense fibrous connective tissue there are large mononuclear cells containing light staining foamy cytoplasm, with small eccentrically placed nuclei and small round cells. In some areas, parts of ducts are seen in a dense and hyalinizing fibrous connective tissue. Scattered through the connective tissue are large mononuclear cells containing rusty brown granules. Many of the ducts are distorted by the prolifera-

Fig 3 Cranioloma showing detail $\times 148$

Fig 4 Same as Figure 3 $\times 500$

tion of the surrounding connective tissue. No atypical proliferation of the epithelium is seen anywhere in the preparation. Occasional groups of epithelial cells, parts of lumina of ducts or acini are seen in the dense hyalinizing fibrous connective tissue stroma. Occasional groups of lumina are lined by flat cells. In the center of some larger area amidst the large mononuclear cells there are slit like structures. In another area there are many giant cells of the foreign body type. In a third preparation a large lumen is seen with frequent infoldings. The surface is partly covered by epithelium and partly denuded. The connective tissue stalks appear like granulation tissue and are loose and densely infiltrated with polymorphonuclear leucocytes and large mononuclear cells. Several such lumina are noted.

In one of the larger lumina there is a dense hyalinizing fibrous connective tissue with many giant cells of the foreign body type and large mononuclear cells with granules of rusty brown pigment. Serial sections show the central mass to be attached to the wall of the duct by a broad pedicle and entirely covered by flattened epithelium proving it to be an invagination. It obviously is a granuloma which occupies the lumen of the duct in the same way as does an intracanalicular fibroadenoma (Fig 2). In another section (Fig 3) small individual complexes can be recognized consisting of a central matrix of spindle cells with small compact oval nuclei. Lying in this mass and arranged radially are a number of oval or fusiform clefts adjacent to which are giant cells of the foreign body type (Fig 4). Surrounding these structures are diffuse collections of small round cells. These aggregates lie in the adipose tissue. Beneath the epithelium of the ducts and in

the surrounding tissue there is considerable infiltration with polymorphonuclear leucocytes and newly formed fibrous connective tissue. Preparations from the lymph nodes show looseness in texture, marked overgrowth of the germinal centers of the lymph follicles, proliferation of the sinus cells, and an engorgement of the sinuses with small round cells, large mononuclear cells, some pink staining material and many eosinophiles.

Diagnosis: Fat necrosis of breast.

CASE 2 No 189832. A 46 year old woman was admitted to the Jewish Hospital of Brooklyn on April 6, 1936 with a history of a lump in the right breast for the past 3 weeks. Occasionally she experienced a sticking sensation in the right breast.

In August, 1932, the patient complained of pain in her lower back. An x-ray examination of the lumbosacral region revealed an osteosclerotic type of infiltration of the fourth and fifth lumbar vertebrae and upper border of the sacrum. At that time a study of the remainder of her osseous system was suggested in search for other malignant foci.

She returned to the clinic in October, 1935 when her chief complaint was pain in the right upper quadrant. A diagnosis was made of chronic cholecystitis. A cholecystographic study revealed a solitary calculus and a poorly functioning gall bladder. She was admitted to the hospital and a cholecystectomy was performed. The pathological report was cholecystitis chronic with cholelithiasis.

Examination on her last admission revealed a middle aged obese woman with fat heavy pendulous breasts (Fig 5). In the lower inner quadrant of the right breast was a tract of stony hardness about 5 cm in diameter.

Fig 5 Fat pendulous breasts

Fig 6 Roentgenogram of mass in breast

eter, fairly well circumscribed, freely movable, and not adherent to the overlying skin or to the deeper structures. This mass was situated deep in the breast tissue. The working diagnosis was that of cyst, with calcification. An x-ray examination of the breast revealed a well circumscribed calcified area (Fig 6). An x-ray film of the skull failed to reveal any evidence of metastasis; there was calcification of the sella turcica. A restudy of the lumbosacral region showed no evidence of pathology in the fourth or fifth lumbar vertebrae. The calcium and phosphorous content of the blood were 11.0 milligrams per cent and 3.8 milligrams per cent, respectively. The cholesterol content of the blood was 308.0 milligrams per cent. Roentgenograms of both humeri were normal. The tumor was excised with surrounding normal breast tissue, under gas oxygen anesthesia. The patient made an uneventful recovery and was discharged cured.

Pathological Report, gross. The specimen consists of two portions of lobulated yellow tissue, 9 by 9 by 3 centimeters and 8 by 6 by 1 centimeter, respectively. In the larger (Fig 7) there is a firm egg shaped mass, 7 by 4 by 2 centimeters. The cut surface of the mass shows it to be composed of a central core of soft, yellow tissue surrounded by a rim of firm white material which in places resembles cartilage. In the nearby adipose tissue there are circumscribed areas of yellow tissue resembling that noted in the mass.

Microscopic. In adipose tissue there are occasional groups of mammary gland acini and ducts. In nearby areas there is a dense hyalinizing fibrous connective tissue and extensive areas of adipose tissue with many large cells with foamy cytoplasm and round nuclei. In some areas there is pink staining homogeneous material and surrounding this

Fig 9

Fig 8 Granuloma showing detail $\times 175$

Fig 9 Same as figure 8 $\times 590$

Fig 10 Calcium deposit in wall of granuloma $\times 40$

Fig 10

and nearly there are occasional giant cells of the foreign body type and a dense infiltration with small round cells and large mononuclear cells. In another preparation there is a broad zone of pink staining fibers with no nuclear stain. Nearby there are collections of cells with granular staining, foamy cytoplasm and round eccentrically placed nuclei of similar cell filled with rusty brown granules (Fig. 9). Coarse collagenous bundles are seen connecting with the dense hyaline area. In the meshes of these bundles with no nuclear stain there are a number of large mononuclear cells with golden yellow granules in the cytoplasm.

Diagnosis: Mammary gland with fat necrosis.

If one were to speculate regarding the cycle of evolution of fat necrosis it can be said that first there is trauma either from external causes or direct pressure of the breasts from their own weight. If the trauma is severe with injury to blood vessels one may see areas of ecchymosis. If the trauma extends more deeply there may be no visible evidence of blood extravasation. The presence of pigment in cells as seen in the section (Figs. 2-8) suggests that there has been hemorrhage.

It is a well known fact that there is a fat splitting ferment (lipase) in the blood as well as in the

fat itself Fat tissue being unstable breaks down very easily into its constituents, fatty acids and glycerine Fat necrosis and fat splitting are two quite different processes, frequently allied, necrosis being the principal event and fat splitting only an accompaniment

Two possible theories of fat necrosis are mentioned by Farr (1) Enzyme action from liberated blood or from the fat cell itself, (2) Simple pressure necrosis from anemia with secondary fat splitting Probably both factors take part in the process, but it is not necessary to postulate enzyme action at all for its production In his conclusion he states that possibly no ferment action is concerned, the etiological factor being simply ischemia Hatfield is one of those who holds firmly that fat necrosis is produced by sterile autolysis

The necrosis of fat tissue accompanied by a splitting into fatty acids and glycerol is considered as a degenerative phase which is closely followed by repair This repair is characterized by the appearance of spindle, round, and giant cells (Menville) In the first case described, the process of repair had gone on to the stage of fibrosis, causing a large hard tumor, which produced a retraction of the nipple The explanation is that since the majority of fat necroses are subcutaneous, the fibrous repair tissue acts like strong cords which have no elasticity but have a tendency to retract In the second case, the end-result of fat necrosis is cyst formation with calcareous deposits Adair states that early in the cycle of fat

necrosis, small cysts may form. After several years these cystic cavities may contain a mixture of small and large calcareous masses If these tumors be left undisturbed, the entire cyst contents and cyst wall becomes a solid calcareous mass

SUMMARY AND CONCLUSION

- 1 Two cases of traumatic fat necrosis are reported
- 2 Fat necrosis must be included in the differential diagnosis of breast tumors
- 3 Clinically fat necrosis more closely resembles carcinoma than other benign lesions
- 4 The treatment is local excision of the tumor mass
- 5 A correct diagnosis can often be made if the surgeon clearly understands and keeps in mind the gross appearance of the lesion

Since writing this article, the diagnosis of fat necrosis granuloma was made in 2 cases before operation, and in both cases the patient was spared radical operation of the breast because of frozen section of a biopsy specimen

AN IMPROVED, RADICAL TECHNIQUE FOR REPAIR OF HYDROCELE TESTIS

MONROE WOLI, M.D. F.A.C.S. New Orleans Louisiana

THROUGH some years of observation and experience in the radical repair of hydrocele testis the author has endeavored to determine the cause of the marked postoperative swelling and induration to be found in the e cases. This complication occasions prolonged hospitalization (not less than 10 days) notwithstanding meticulous postoperative care by elevation of the scrotum and the application of cold or heat. A suspensory of sufficient size is unobtainable.

As so little trauma is caused by the enucleation of the sac and testis in the Wyllis Andrews (botle operation) technique (2) or the numerous procedures described by Bickham, it is reasonable to conclude that in the uncomplicated (non infected) cases there must be some disturbances in the circulatory and lymphatic systems, sufficient to cause the marked reactions encountered. Muschat's work on 'Testicular Torsion' would seem to corroborate this idea as does later work by McKenna and Ewert on "Management of Undescended Testis."

In 1932, the author began experimentation with radical procedures, incompletely enucleating the sac and testis by freeing only the anterior half or two-thirds of the sac without detaching the gubernaculum.

The following technique was finally adopted: (1) The sac is partially separated from the fascial planes and opened to evacuate the contents. Fig. 1a—the dotted lines mark the portion of the anterior wall in process of excision. (2) Interrupted, interlocking figure of eight sutures are placed around the edges, their ends being grasped in forceps and the sutures not being tied until all have been placed around the whole cut edge of the sac (Fig. 1b). These figure of eight sutures act as hemostatic agents and when properly tied contract the sac wall about the epididymis and posterior surface of the testis. When the figure of eight sutures are tied, the one at the lower pole of the testis (gubernaculum) is tied first, then that on each side alternating until all sutures have been tied. An assistant should make slight pressure against the testis through the posterior scrotal

wall in order to elevate the testis during the tying of the sutures. (3) Figure 1c illustrates the appearance of the incomplete repair of the sac wall with traction forceps on the lower mesial portion. The infundibular (deepest) fascia is noted with tunica (sac wall) in the partially tied figure-of-eight suture. (4) The dartos and skin are closed with a continuous, running suture (Fig. 1d). More recently a continuous mattress suture has been used for the skin closure. Hemostasis is essential for success, notwithstanding the fact that only an occasional ligature is required in the dartos. Plain No. 0 catgut is used throughout.

Local infiltration with novocain solution $\frac{1}{2}$ per cent was discontinued after the first 6 cases because of the edema in the scrotal wall although there was no induration or swelling of the testis. Eutocain, 50 milligrams boiled in 2 cubic centimeters normal saline solution, as a spinal anesthetic was next used with gratifying results. More recently an epidural injection of novocain, 2 per cent 20 to 30 cubic centimeters has been used with much less risk. In one of the early cases, in a child, in which interrupted hemostatic mattress sutures and not figure of eight sutures were used under ethylene anesthesia recurrence was reported.

In the uncomplicated cases, under spinal epidural or gas anesthesia, a medium sized suspensory may be applied and the patients may be allowed out of bed and be discharged from the hospital in 36 to 72 hours after operation without induration or swelling of the testis.

In 28 cases in which the interrupted interlocking figure of eight sutures were used 19 replies report no recurrences. One patient reporting partial recurrence has since been examined and no indication of fluid in the scrotum was found. One subsequent report has been received showing no recurrence giving a total of 20 replies to 28 questionnaires without a single recurrence.

The author has had the opportunity to explore one of his first cases operated upon by this procedure 4 years previously. On this occasion the patient presented large bilateral masses in the scrotum which were irregular, firm, and nodular, and which transmitted light. The masses proved to be spermatoceles. It was very interesting to

From the Urologic Service, Charity Hospital, Toussaint Infirmary and New Orleans Women's Hospital.

Fig 1 a, Anterior half of sac exposed b, Interrupted interlocking figure-of-eight sutures in sac wall c, Appearance of repair of sac wall d, Closure of dartos layer of skin

note the result of the previous hydrocele repair. The surface of the tunica vaginalis was smooth and glistening, with considerable thickening behind the testis, where it had been drawn along the vas and lower end of the cord.

SUMMARY

- 1 A new, radical technique for repair of hydrocele testis is reported.
- 2 Epidural or spinal anesthesia is preferred for adults.

3 Following exposure and excision of the anterior half or two-thirds of the sac, interrupted, interlocking figure of eight sutures are applied to sac edges. The dartos and skin are closed with continuous sutures.

4 Patients are able to walk out of hospital, wearing medium sized suspensories, within 36 to 72 hours after operation.

5 In a series of 28 cases, 20 questionnaire replies, including 1 case explored 4 years after operation, show a perfect result.

The author wishes to express his profound appreciation to Mr W. Branks Stewart, artist, Louisiana State University Medical Center for the drawings, and to Miss Nan Gayle Hopkins, Social Service Department, Charity Hospital for her interest in the questionnaires reporting results.

FOLLOW-UP OF HERNIA REPAIR

ALFRED B. LONGACRE, M.D. New York, New York

REPORTS of the results of the operative treatment of hernia from hospitals and surgical clinics are frequently seen in the surgical journals. Preceding the last quarter of the nineteenth century the recurrence of hernia following operation was the usual result. Halsted (17) in a paper quotes from an article written by Bull in 1890, at this time two methods of repair are being used with nearly equally poor results. Bull from 1883 to 1885 operated for the cure of hernia by what he called Socin's method, namely ligature and excision of the hernial sac and from 1885 to 1889 he employed Bank's method which consisted of ligature and excision of the sac plus suture of the pillars of the external ring. Recurrences were noted in 27.7 per cent of the cases repaired by Socin's operation and in 40 per cent of those treated by Bank's procedure. These recurrences were all noted in the first year after operation. In 1890 Halsted (15) reported the operation which now bears his name. This paper was shortly followed by a similar article by Bassini (2) and in 1895 Ferguson (10) summarized the methods of surgical procedures for the cure of inguinal hernia which were in vogue at that time. He also gave his modifications of the Bassini and Halsted techniques and in the same paper reported a technique for the cure of femoral hernia. Since the publication of these papers the reported incidence of recurrence of hernia has been fairly uniform, ranging from a low of 1 per cent at the Mayo Clinic

(22) to figure, covering a fairly wide range above this. With Bassini's and Halsted's procedure as a groundwork operators have at various times introduced modifications and changes in the detail of the technique. These changes have met with indifferent success. Bloodgood in a review of cases done with the Halsted technique reported recurrence of 5.2 per cent. Since this early report very few summaries have shown much if any improvement.

The cases in this report are those in which operation for the cure of hernia was done in the First and Second Surgical Divisions in the Presbyterian Hospital in New York City. Only those cases with a follow up by examination of patients in the Vanderbilt Clinic will be included in an analysis of the statistics. Private and semi-private cases are excluded as their follow up data are very incomplete and in many instances entirely lacking. The types of hernia discussed are inguinal, femoral, umbilical and epigastric. Ventral incisional or postoperative hernias are not included.

It is important to know the method employed in following the cases after discharge of patient from the hospital to evaluate correctly post-operative results. Many writers fail to mention the system of checking their cases, while others apparently include written reports either from the patient or some outside physician. The inaccuracy of this latter method is clearly shown in a series which reports a recurrence of 3.4 per cent in the cases followed by letter as against an 8.3 per cent recurrence in the patients which were examined in their own follow up clinic. With such

discrepancies occurring it is obvious that the only reliable method of obtaining accurate information of the end-results of herniorrhaphies is by adequate and complete examination of the patient.

All of the patients treated in the wards of the Presbyterian Hospital are, upon discharge, given an appointment to return to the follow-up division of the Vanderbilt Clinic, which is the out-patient department of the hospital. Here, they are interviewed and examined with three main objectives in mind: anatomical result, symptomatic result, and economic result. Accordingly the findings of each of the three points are given a score ranging from 1 to 4, a 444 result being the highest possible. The patients in this series were in most instances examined by the surgeons who performed the operation. This, however, was not always possible, consequently many of the patients were checked by more than one surgeon. With the exception of instances in which it is important to include those who failed to keep their appointments in the follow-up clinic, only the patients so followed are included in the analysis of the figures. For convenience and to avoid confusion, all hernias, irrespective of complications which would give them a lower score, will be designated as a 444 result in the tables and elsewhere, unless there is recurrence, in which case it will be scored as either "recurred" or "rec" instead of the usual 044.

This series includes 752 patients operated on for hernia during the 6 year period between January 1, 1930, and December 31, 1935. These patients are all adults as those under 12 years of age are operated on in the Babies Hospital. A total of 925 hernias were repaired, all but 88 of which returned for follow-up examinations. 827 were seen at least once, 589, or 72.3 per cent, returned over a period of 12 months, and 338, or 41.5 per cent were followed at least 24 months. Sixty-six, or 8.2 per cent, of the hernias have a follow-up period of 5 years or longer. In this series the postoperative interval between repair and the time of recurrence is somewhat longer than those given in other reports. Judd found that 70 per cent of his recurrences were noted in the first 6 months and 90 per cent in the first 12 months. Erdman, in 1923, reports that 73.9 per cent of his recurrences took place in the first 12 months and 98.6 per cent in the first 24 months. In our cases 72 per cent of the recurrences were noted at the end of 12 months and 87.2 per cent of the recurrences within the first 24 months.

The surgical procedures in these cases were performed by 60 different surgeons, 38 of them being the senior house officers serving their last

4 months as interne, the 22 remaining operators being members of the attending staff. The senior house officer is assisted by a member of the attending surgical staff in every operation. In comparing the two groups of operators it was found that the cases operated on by the attending surgeons had a 6.3 per cent recurrence as against a 6.8 per cent recurrence in those repaired by the members of the house staff.

The difference in the percentage of recurrence as related to the type of anesthesia used in the operation is very small. general anesthesia, 7 per cent, spinal anesthesia, 7.5 per cent, local anesthesia, 8 per cent. In 9 cases the anesthesia record was not on the chart. It is interesting to note 2 recurrences in this group. In his report, Taylor found the incidence of recurrence higher in those cases repaired with local anesthesia, adding that a local anesthetic does not interfere with or delay wound healing. Davis reports the low figure of 2.3 per cent recurrence in hernias repaired with local infiltration or nerve block anesthesia.

That the operation for hernia carries a minimal risk of fatality is probably very true. Taylor, in 1920, reports 2,486 cases of inguinal hernia with 19 deaths, or 0.76 per cent. Davis reports 8 deaths in a series of 1,756 for a 0.44 per cent mortality, while Erdman reports a low mortality of 0.32 per cent. In this series there were 10 deaths in 752 patients which gives a 1.3 per cent mortality. In the simple or not strangulated group there were only 5 deaths, or 0.69 per cent, as against 17.8 per cent in the strangulated group. Eight of the 10 deaths occurred in patients over 50 years of age, the 2 others being in patients of 35 and 38 years of age. Eight of the patients died after the tenth day, 2 on the twenty-third day, both of which had been transferred to the medical wards, one in cardiac decompensation, the other following repeated coronary attacks. There are 4 cases of acute hernia which had been strangulated 24 hours or longer, 3 of which had to have intestinal resections. Some of the complications noted as contributory factors interfering with recovery are cardiorespiratory failure, 1, coronary occlusion, 1, cardiac insufficiency, 1, ileus, 1, pancreatitis, 1, gastro-intestinal hemorrhage, 1, peritoneal abscess, 1, and pneumonia, 2.

In spite of repeated statements that the operative cure of hernia is nearly an ideal surgical procedure, in that the results are good and the mortality so low as to be negligible, the mortality statistics in this series are sufficiently high to warrant serious consideration of all factors pertaining to the general condition of the patient and

a careful weighing of the benefits to be derived in the case in hand before suggesting an operative repair. It serves to re-emphasize the fact that even the simplest surgical procedures carry a sufficient risk, so that they should be advised only after considering all the facts concerned.

It has already been mentioned that the patients in this series fall into the so-called adult group. It has long been known that patients of indirect inguinal hernias appear for operation at a younger age than do patients with other types of inguinal or femoral hernia. In the indirect group 65 per cent of the patients were under 35 years of age and only 26 per cent were over 45. Fifty-one per cent of the patients with direct inguinal hernias were under 35 years, while 46 per cent were over 35. The other groups of inguinal hernias, namely sliding and indirect direct, fall into an intermediate age group.

The serology was determined in 667 patients, 30, or 4.49 per cent, had a 4 plus Wassermann reaction, 2 of which had a recurrence of their hernias. There are 257 cases in which the Wassermann reaction was either not reported or reported as equivocal. A truss was worn for 287 of the hernias, 26 of the hernias which recurred had at some time or another been supported by a truss. The percentage recurrence of those who had worn a truss was 9.3, which is slightly higher than that for the entire group. The weakening and scarring of tissues which is associated with the cases of hernia which had been supported by a truss was also noted in these cases. Two patients gave a history of having worn a truss from childhood for a hernia which was present at that time. Both these patients were later admitted for a repair of a hernia on the side opposite to that for which a truss had been worn and in neither case was a hernia noted on the side which had been treated by the wearing of a truss.

Wound infections were noted in 53 cases with follow-ups on all but 2. Most of these infections were trivial or stitch abscesses, the latter being

so designated in 20 wounds. Only 2 of the infections were listed as serious. Twelve, or 2.55 per cent of the cases repaired with silk, showed some infection while 37, or 15.04 per cent of the cases repaired with catgut were infected. Hematoma was noted in 17, or 1.8 per cent of the wounds, all but 3 of which were followed and no recurrences noted. Silk was the suture used in 11 of the cases with hematoma. This gives a 2.3 per cent of the total cases repaired with silk. Five, or 2.3 per cent repaired with chromic catgut developed a hematoma.

Detail analysis of the cases repaired under local anesthesia shows some interesting facts. In 107 cases local anesthesia was used either by itself or in combination with a general anesthesia. Three deaths occurred in this group. In 83 cases in which operation was done under local anesthesia the suture material was either silk or catgut. In the 54 repaired with silk alone there were 1 infection, 4 hematomas and 1 recurrence while in the 59 cases repaired with catgut there were 6 infections, 4 recurrences and no hematomas.

The frequency of other postoperative complications and their relationship to the incidence of recurrence are given in Tables A and B. The appendix was removed at the same time and through the same wound in 6 cases of right inguinal hernia with 1 recurrence. 16 hydroceles were excised, the wall of the intestine was pierced with a needle in 2 instances, the bladder was accidentally opened in 3 cases, in 3 cases the vas was accidentally cut, 4 cases had an orchidectomy and vasectomy and in 1 case the vas was crushed. In addition there were 2 cases of undescended testicle and 8 with the varicocele.

Of the 925 hernias, Table I, 816 belong in the inguinal group, with a follow-up on 734. 703 were in males and 86 in females, the ratio of almost 9 to 1. In the female group the hernias are divided as follows: 71 indirect, 7 direct, 3 indirect direct, 1 sliding and 5 in the recurrent group. There are 62 femoral hernias, all but 5 of which returned to

TABLE I—ANALYSIS OF CASES

	Male	Female	Total	Not followed	Recurred	Died	Not followed per cent	Re-curred per cent	Died per cent
Indirect	493	71	534	60	26	1	11.2	5.6	0.18

Inguinal strangulated	13	5	18	1	1	3	5.5	5.8	16.6
Femoral strangulated	3	7	10	—	1	2	—	10.0	20.0
Totals	766	159	925	83	57	10	9.6	6.8	1.08

the clinic for examination, making a total of 57 followed cases. In the umbilical and epigastric group there are 19 cases, 9 male and 10 female. There are 28 strangulated hernias, 18 of the inguinal type and 10 in the femoral group, the male to female ratio remaining about the same as in the other groups.

The 816 inguinal hernias are divided into the 6 following groups: the indirect group of 534 hernias, with 473 followed cases, 121 direct inguinal hernias with 114 followed cases, 56 indirect-direct inguinal hernias with 49 followed cases, 29 sliding hernias with 26 followed cases, 76 combined hernias with 67 followed cases. The incarcerated hernias are included with the reducible hernias of their respective types. However, the acute or strangulated hernias are listed separately and will be discussed later. Recurrences are found in 26 or 5.6 per cent of the indirect inguinal hernias,

8 or 6.9 per cent of the direct inguinal hernias, 5 or 10.2 per cent of the indirect-direct inguinal hernias, 4 or 15.3 per cent of the sliding hernias, 8 or 11.9 per cent of the recurrent hernias.

Bilateral and double hernias occurred in 152 or 20.7 per cent of the patients. In this paper the term double hernia is limited to designate those cases of bilateral hernia in which the hernias were different one from the other on either side. There are 101 patients with bilateral hernia and 37 with double hernia. These figures do not give the correct incidence of bilateral or double hernia, for in addition there are 67 patients who had a hernia on the side opposite to that which was repaired in this series. There are also an additional 12 cases of double hernia in which one or both sides belonged in the recurrent group, 2 cases in which a double hernia was found on the same side. These last 2 cases were both direct inguinal her-

nia with associated femoral hernia. Table III gives the number and frequency of recurrence as found in this series of bilateral hernias. Bilateral hernia occurred 70 times in the indirect inguinal group and 24 times in the direct inguinal hernia group. There are no cases in which a sliding hernia was bilateral, but it did appear in 7 of the double hernias. Table IV separates and gives the relative frequency of double hernia and also indicates the most frequently found combinations of double hernia.

The analysis of the cases of bilateral and double hernia is divided into three groups as illustrated in Table III. Recurrent hernias are not included in this table. In the first column the patients who had both sides repaired at one operation are listed while the middle column gives those repaired at separate operations on the same hospital admission, and column three listing those who had either side repaired on separate admissions. In the first of these groups 9 or 5.3 per cent of the hernias recurred in the second group 2 or 3.8 per cent and in the last group 4 or 11.7 per cent, recurred. This series is too small for definite conclusions but seems to indicate that those which were repaired at separate operations had a better prognosis.

Transverse and Judd incisions were used in 16 cases, recurrences being found in 3 of them. There were 6 wound infections in the cases of bilateral hernia which were repaired at one operation and

5 infections of those which were repaired at separate operations. Three of these infections were in cases which had recurrences of the hernia and these belong to the group in which the operations were performed on different occasions. As there are so few cases in this series of bilateral hernia, any attempt to correlate, with the incidence of infection, would only be misleading, whether or not both hernias were repaired at the same operation or at separate operations.

Suture material in hernia repair has been much discussed in the literature. The points which have been emphasized is the necessity of having a material of sufficient strength and durability to hold the wound together over a long enough period of time to allow it to heal solidly. The separation of the line of repair has been given as one of the most frequent causes of recurrences. Halsted varied his choice of suture material, however, most of his hernias were repaired with silk. He reported one series in which he used silver wire exclusively. Table II gives the number of hernias repaired with either chromic catgut or silk with the incidence of recurrences of each. This table does not include hernia which were repaired with chromic catgut and silk combined, linen or linen and chromic combined. Silver wire was used on one occasion. Irrespective of the type of hernia a marked and impressive lower incidence of recurrence is found in the cases repaired with silk compared with those repaired with chromic catgut. In our series silk was used in 496 hernias, 3.4 per cent of which recurred. Chromic catgut was used in 2,0 with 12.5 per cent recurrent. In the direct inguinal group 89 of the hernias were repaired with silk and 22 with chromic with 4.49 and 13.6 per cent recurrences respectively. There were 15 indirect inguinal hernias repaired with silk and

153 repaired with chromic, the incidence of recurrences being a 2.16 and 9.8 per cent, respectively. The greatest difference is noted in the sliding hernias 35 of which were repaired with silk and 12 with chromic, 6.6 per cent of the silk repairs recurring and 25 per cent of the chromic recurring. The recurrences in the recurrent hernias are comparable but slightly higher than those of the simple hernias. Glenn and McBride reported a series of 500 hernias repaired with silk with the following percentage of recurrences: 2.3 in the indirect inguinal group, 6.21 in the direct inguinal group. In 1919 Masson reported 7,016 cases of inguinal hernia repaired with 20 day chromic catgut with a less than 1 per cent recurrence in the cases with cord transplantation and slightly more than 1 per cent in the cases in which the cord was not transplanted. He does not give follow-up statistics, consequently, it is impossible to determine how many of his patients were examined at the Mayo Clinic. His figure would be more impressive if he had found this low recurrence in his followed cases.

Silk as a suture material is being more frequently used in clean surgical cases. In this series twisted A or C silk or finely woven Deknatel silk was used throughout. That catgut varies in its durability and lasting qualities has been very clearly shown by Kraissl in a report on the absorption rate of catgut. In this article he also shows that there are individuals, appearing more frequently than one would expect, who are sensitive to catgut. In these cases there is a definite reaction about the sutures and in all cases of wound disruption in allergic patients in which

catgut was used and the skin test for sensitivity made, the patients gave a positive reaction. He advocated the use of the skin test of all patients for sensitivity to catgut before using it. If this is done in cases of hernia repaired with catgut the difference in the incidence of recurrences as compared to the incidence of recurrence in those repaired with silk might be much less.

The hernias comprising the group repaired with suture materials other than those described are too few in number to warrant further discussion. There are three recurrences in the cases in which the choice of suture was not mentioned and two recurrences in the strangulated hernias.

The operations in this series can not be classified in the usual manner. Each operative note describes the repair specific to that case. It is, therefore, impossible to list the repair as a typical Bassini, Halsted, Ferguson, Wyllis Andrews or any other type. The remainder of the discussion of the inguinal hernias will be limited to the main points described in the operation notes.

The treatment of the hernial sac consisted of freeing it from the surrounding tissue. If adhesions were encountered these were severed by either blunt or sharp dissection which was carried as far as the internal ring. The sac was then excised and ligated and in many instances the stump of the sac was transfixed under the internal oblique muscle. There are no cases in which the sac was used as a tampon as advocated by MacEwen and Ferguson.

The transversalis fascia has been considered one of the first lines of defense in the repair of hernia since the days of Halsted and Ferguson. The

usefulness of this layer varies greatly with individuals. It is frequently so thin that it is of little value while in other cases it is difficult to define it as a separate layer. Anatomically it is easy to understand the importance in the treatment of this layer of tissue as it forms the first and probably the most important line of defense against recurrence. However stress should be laid on the repair of this fascia in the region of the internal ring for it is in this region that this fascia is the weakest and consequently the site of most recurrences. The triangle formed where this fascia allows the cord and its structures to emerge from the abdominal cavity should be very carefully repaired. Elsewhere one of the following three methods which will be mentioned can be used to strengthen this layer of fascia deep to the cord.

This fascia was used in 450 hernias with 32 or 7.1 per cent recurrences. It was used in one of the following methods: suture of the fascia to Poupart's ligament and plication. The effectiveness of the use of the fascia is tabulated in Table V. From this it can be seen that it did not materially lower the incidence of recurrences in those cases in which attention was paid to the transversalis fascia. In the indirect inguinal group suturing of the transversalis fascia to Poupart's ligament seemed to be most effective with only 9 or 5.5 per cent recurrence while in the direct group of hernias those in which the fascia was plicated there was only 1 or 2 per cent recurrence. It is very difficult from this series to come to any conclusion as to the value of the use of the transversalis fascia in preventing recurrences in inguinal hernias. If the operative notes had described in detail the treatment of this layer of tissue at the internal ring a more detailed and critical analysis could have been made. In this connection it is interesting to note that in the cases in which the treatment of the transversalis fascia was not mentioned there were only 19 or

6.9 per cent recurrence, a figure which is slightly lower than that in which the fascia repair was used.

In practically every instance the conjoined tendon and the lower border of the internal oblique muscle was sutured to the shelving margin of Poupart's ligament. Those cases in which the conjoined tendon was either obliterated or too narrow to make its use effective will be discussed under the living fascia sutures.

Halsted and Bassini simultaneously described transplantation of the cord as an important step in hernia repair. In Bassini's operation this was transplanted to lie immediately beneath the aponeurosis of the external oblique muscle. Halsted transplanted the cord subcutaneously in his early cases later modifying the position according as he found the pathology. Table VI gives the frequency of cord transplantation with the incidence of recurrence. In 393 hernias it was left under the external oblique and in 122 hernias it was placed superficial to this structure. Included in the instances in which it was left subcutaneously are a few cases in which it was left between the leaves of the imbricated margins of the aponeurosis as described by Byles and Evans. Transplanting it under the external oblique was most effective in the cases of direct inguinal hernias with the recurrence of 2.7 per cent. The group of hernias in which the cord was placed to lie subcutaneously had in all but one group a higher incidence of recurrence than in the other cases when it was left under the external oblique. There are only 40 cases in which it was definitely stated that the cord was not transplanted, 35 of which were indirect inguinal hernias 1 of which recurred. In 82 cases the treatment of the cord was not mentioned. In 2 cases the cord was treated much after the manner described by Torck (27) with separation of the vas from the veins of the cord in neither was there recurrence. Blood

good's procedure of excising the veins was performed in a few cases. This was limited to the cases in which the spermatic cord was unusually large. The treatment of the cord was not stated in most of the operative notes of the recurrent hernias. The cases in which the cord was excised with orchidectomy are listed elsewhere.

Living fascial sutures were used in 139 hernias. In 74 cases the suture was taken from the lower margin of the aponeurosis and in 50 a strip of the tensor fascia femoris was used. In 15 cases a strip of either the rectus muscle or fascia was used to strengthen the medial angle of the repair. The use of the rectus fascia was limited to those cases in which the conjoined tendon was either obliterated, narrow, or so frayed that it was of little value. Recurrences were noted in 5, or 6.7 per cent of the cases repaired with a strip of the external oblique aponeurosis, in 8, or 16 per cent of the cases repaired with fascia lata, and in 2, or 13.3 per cent of those in which the rectus muscle or fascia was used. Fascia lata was used more frequently in the cases of recurrent hernia, this may possibly explain the higher incidence of recurrence in this group. In many of the cases in which repair was done with fascial sutures and there was recurrence the operative note describes the previous fascial repair as being satisfactory.

Sliding hernia were found in 3.1 per cent of the series. This is a somewhat lower incidence than noted in other papers. The viscera found in these hernias are: cecum, 5 times, bladder, 4, and sigmoid, 9. In 2 of the cases the bladder was accidentally opened. There were 76 recurrent hernias with 11.9 per cent recurring. This figure is lower than reported in other papers.

In the group of 72 femoral hernias, 10 were strangulated, 4 recurred, and 3 patients died, 5 patients failed to return to the follow-up clinic and are omitted from this discussion. Thirty-six of the hernias were repaired through incisions made below Poupart's ligament, 18 from incisions above and paralleling the ligament, 4 so called vertical incisions, all of which probably belong to the first group, 5 combined incisions which ran from below up and lateral across the ligament, 3 rectus incisions, and in 6 cases the position of approach was not clear. Bassini's technique of suturing the pectineal fascia to Poupart's ligament was done in 37 cases. The other repairs were done as follows: in 2 cases Poupart's and Cooper's ligaments were brought together, 3 cases in which the defect was closed with a purse-string suture, 3 in which the defect was closed from within the abdomen and in 12 the method of repair was not stated in detail. Recurrence was

noted in 1 case in which repair was done by suturing Poupart's ligament and the pectineal fascia together; the 2 other recurrences in the group were in the cases in which repair was not clear. There were 10 strangulated and 30 irreducible hernias in this group, 2 of the strangulated hernias were of the Richter type.

The mortality analysis of the strangulated hernias has previously been discussed. That femoral hernias strangulate more frequently than inguinal hernias is a well known fact. This was also noted in this series, there being 10 strangulated femoral hernias in 72 cases as compared to 18 strangulated hernias in the larger inguinal group. In 5 of the 28 cases the intestine had been compromised to such an extent that resection was imperative. In each case it was the small intestine which was resected. Duration of acute symptoms preceding operation varies from 3 hours to 5 days, the greatest number presenting themselves within 20 hours of onset. In those patients who died the hernia had been strangulated 24 hours or longer. The 3 patients requiring resection died, all 3 had had symptoms longer than 48 hours.

As there are only 9 cases of umbilical hernia and 10 cases of epigastric hernia only a little valuable information can be gained from their analysis and consequently they will be discussed together. There were 2 cases of umbilical hernia in the male and seven in the female, while in the epigastric group 7 were in males and 3 were in females. Only 2 of the umbilical hernias were in patients under 35 years, 4 patients were between 36 and 45 years with 1 occurring after the 45th year. The age incidence in the epigastric group is almost identical and will not be repeated. The technique of horizontal overlap as described by Mayo was used in 6 cases of umbilical hernia, the 3 others being repaired by simple approximation of the edges of the defect. Six of the epigastric hernias were also repaired by approximating the edges of the defect without an attempt at either a vertical or a horizontal overlap. Silk was used in 8 cases of epigastric hernia and only once in umbilical hernia. Chromic catgut sutures were used in 7 cases of umbilical hernia and in only one of the epigastric hernias. Kangaroo tendon was used once as well as chromic and silk. There was one infection in the umbilical group, and three of these patients were drained. All of the wounds in the epigastric hernias healed *per primam*. One of the epigastric hernias recurred.

SUMMARY AND CONCLUSIONS

In concluding it might be stated that the purpose of this review is to summarize our cases of

hernia and to present the incidence of recurrence and of certain factors as they were found in the cases which did not recur as well as in those which did recur. A complete metamorphosis in hernia repair took place following Bassini's and Halsted's papers describing their techniques which today are still the most satisfactory and have been changed but little since the publication of their articles.

The difference in the incidence of recurrence in all types of hernias repaired with silk as compared to those in which chromic catgut was used is very striking. Studies, which are now being made, indicate that the failure in those cases in which repair was accomplished with chromic catgut can partly be explained as being due first to a defect in the suture material, second, variability of the absorption rate, and third patient's sensitivity to catgut.

Better results were obtained in those cases in which the cord was left under the external oblique aponeurosis.

This series of cases re-emphasizes the fact that if a technique can be so elastic as to meet the variations anatomical and pathological, found in hernias the perfect hernia repair is yet to be described.

CONTROLLING OPERATING ROOM STERILIZERS

IT will probably come as a surprise to some, if not to many, surgeons that today, nearly a half century since the advent of aseptic surgery, materials frequently are delivered to the operating room which, from the nature of the procedure of sterilization, could not properly be considered sterile

A number of items enter into the reasons for this unfortunate and even dangerous situation. In the first place, there is no clearly established rule for deciding what personnel should do the sterilizing and one sees this important process carried out by persons ranging from janitors and busboys, through a changing personnel of student nurses, to experts employed to do nothing but sterilize hospital goods. Many persons who sterilize these supplies have not the slightest notion of the fundamental principles involved nor even rudimentary knowledge of the mechanical equipment used. A second reason is to be found in the equipment, not necessarily the apparatus

itself but its state of repair. One extreme case recently was noted wherein for days no steam had entered the sterilizer because of a plugging of the steam valve, the nurse not having noted the failure of the gauge to register. A third factor, and probably the most important from the practical standpoint, is failure to appreciate the obvious fact that the pressure gauge is a safety device to help prevent explosion and that the important factor so far as sterilization is concerned is temperature. In this connection few seem to know that a mixture of steam and air reduces the temperature without affecting the pressure and that only in the presence of pure steam is the proper pressure-temperature ratio maintained. To obtain an atmosphere of pure steam requires thorough exhaustion of the chamber and this directs attention to a fourth reason for lack of sterilization; namely, that manufacturers frequently have not provided adequate means of exhausting the air and condensed steam from the inner chamber. The by-passes are frequently small and easily plugged with debris or lime. Far better is it to open the door and let the steam flow freely into the room at the beginning than to fail to exhaust the chamber at the end. The use of a vacuum is begging trouble for this tends to suck in air through any small leak. It is far better to exhaust air by steam pressure than by air vacuum. A fifth factor is found in the practice of overloading the sterilizer with materials, especially in tightly packed packages. This precludes the ready access of steam to the materials and causes great variation in the time-temperature ratio in individual packages, making it necessary to exceed the required time for running the sterilizer in order to assure sterilization. It must

be constantly remembered that the penetration of steam into packages varies with the nature of the material, their positions in the chamber, and the tightness with which they are packed.

The important point is to be sure that each piece of material has been submitted to adequate temperature for an adequate time. Unfortunately there is no universal agreement on this matter. How short a time may be considered acceptable to some may be seen from recent specifications submitted by one bureau calling for devices which will indicate "sterilization" at 250 degrees F. for not less than 5 minutes and not more than 6 in a light surgical pack. While it is questionable if this is enough time even for test tube experiments, it clearly gives no margin of safety, which certainly should be at least thrice the time required and some would advocate more. While the exact time-temperature relationship may be considered of academic interest only, it is clear that whatever it is one should know that materials have been submitted to a predetermined temperature for a predetermined time. This can be known only by the use of some reliable indicator of which there are three types.

The first of these indicators is a recording temperature clock. This is a positive device and the bulb of the thermometer should be placed in the exhaust steam line. The instrument is expensive and troublesome and does not necessarily give the temperature of the inside of a typical package. Relatively few sterilizers are equipped with the device or are likely to be.

The second device is a glass tube in which a chemical of fixed melting point is sealed. If these tubes are tested in an oil bath the chemical melts in a few seconds at 250 degrees F. or even at lower temperatures. It is assumed by some that when these tubes are

placed in gauze packages they act as lag thermometers. The time of lag is certainly variable and under no circumstances does the chemical take longer than a few minutes to melt. If there is any margin of safety at all it is slight and, under many conditions, the chemical melts before the minimal time and temperature have been maintained. If these tubes are used, several should be employed in each load and they should be employed with full knowledge of their obvious limitations and of the expense involved.

Finally there are the ink indicators, which are fixed as to the relation of time and temperature and must be submitted to moist heat for a given time at a given temperature before a change of color occurs. One such indicator has several inks on it, which turn at five minutes, twelve and a half minutes, twenty minutes, and more than twenty five minutes, respectively. These are reliable, sharp at end point, and permit one to know the exact condition under which the sterilization has been accomplished. If one of these devices is inserted in a pack which is then placed at the coldest place in the sterilizer, one may be assured of adequate sterilization if the ink has turned. The margin of safety desired can be readily controlled. Certainly if the twenty minute ink has turned, the margin is fully adequate and the few extra minutes will not cause any great inconvenience. For rubber gloves, which have first been adequately prepared before autoclaving, twelve and a half minutes is sufficient. The total length of time the sterilizer will need to be steamed vary with the particular conditions attending the procedure.

More recently an entirely new device has been invented and used. This consists of a time clock which will not permit the door of the sterilizer to be unlocked until a certain temperature has been maintained for a cer-

tain length of time The expense and intricacy of the device, the fact that it is marketed at present by only one firm, and will not routinely test the condition of individual packs, will naturally limit its use.

What is urgently needed is for some responsible body to set up standards for these sterilizer controls, for there is much difference of opinion now as to the necessary time-temperature ratio Whatever ratio is agreed on it should carry with it a margin of safety adequate to cover all the usual slips in technique. The indicator should be required to have a controllable lag time, a sharp end point, and to be stable, easily used, and cheap It will be desirable to have to use only one indicator to the load. No better standardizing body could be suggested than the American College of Surgeons and the importance of the matter would justify its attention to this problem

T B MAGATH

THE ENDOMETRIAL BIOPSY

IT is interesting that the term "biopsy" has come to mean to some a method of obtaining tissue for examination. It is essential that the term be understood to refer to the diagnostic (usually microscopic) examination of a piece of tissue removed from a living subject Examination of the tissue and the information thus gained are, of course, the significant features. The term has nothing to do with the method employed to obtain tissue nor with the type of instrument used When the term "endometrial biopsy" is used herein, therefore, it implies that the tissue may be obtained either by diagnostic dilatation and curettage or by means of any instrument with which satisfactory endometrial specimens can be obtained Since the information gained by the proper examination and interpretation of endometrial findings is one of the features

requisite for the intelligent management of menstrual dysfunctions, it seems justifiable to restate briefly some of the helpful steps in this procedure

It becomes increasingly evident that far more information can be obtained from such a diagnostic procedure than mere exclusion of a malignant process which in itself is, of course, important Until the last few years, however, in that large group of cases in which no malignant change was encountered, the tendency was prevalent to label all of these non-malignant tissues as hypertrophied or hyperplastic endometrium. It is known now, however, that the microscopic appearance of the endometrium holds the information so essential to the proper interpretation of ovarian function regardless of whether the function is normal or abnormal. Endometrial biopsy has limitations, however, in that it fails to give the information necessary to allow the dysfunctions to be classified on a basis of etiology This merely means that the reflection of the ovarian disturbance in the endometrium is the same, regardless of whether the cause of the ovarian disturbance comes from within the ovary (primary ovarian deficiency) or whether the cause of the disturbance in the ovary is secondary to disturbed physiologic function of the pituitary or thyroid glands which so definitely control ovarian activity (secondary ovarian deficiency) Endometrial biopsy, however, has proved to be the greatest single aid in determining whether the ovarian deficiency is partial or complete.

It is known, not only from clinical observation but also from the brilliant experimental studies of those concerned with these problems, that the regenerative phenomena which occur monthly in the endometrium are controlled by the action of the normal output of the estrogenic principle, a product of the follicle, and that the differentiation of this

tissue into a functioning unit is directly dependent on the action of the product of the corpus luteum, progesterone. The recovery of progesterone from urine of women was delayed for a considerable period. The explanation of this lies in the fact that the product of the corpus luteum, unlike the product of the follicle (estrogen), is excreted as a changed compound to which has been given the name pregnandiol. To Venning and her associates is credited this excellent observation which has recently been confirmed by Wilson, Randall, and Osterberg. Before isolation of this product it was possible, however, by observation of the endometrial histologic characteristics, to predict the almost exact time of appearance in the urine of this recently isolated material. The prediction, of course, was made by observing the changes in the histologic pattern of the endometrium which follow almost immediately the period of initial activity of the corpus luteum.

Endometrium is the only human tissue in which study of regeneration has been possible. Regeneration of endometrium, just as is true of regeneration of any tissue, follows a definite histologic course of events. From observations of this process have come the interpretation of abnormal ovarian activity in terms of what normally occurs in regeneration. The first half of the regenerative process (menstrual cycle) consists in active proliferation of the tissue and this proliferation is controlled entirely by the action of estrogen, the product of the normally functioning follicle. As has been stated, differentiation of the endometrium into a functioning tissue depends on the principle of the corpus luteum, progesterone. It follows then that irregularity in the functional balance of the ovarian hormones which control this process is followed by irregularity in the regenerative phenomena controlled by these hormones. This in turn results in men-

strual dysfunction either bleeding, amenorrhea or sterility. If, therefore, the intention is to learn something concerning the activity of these hormones on the endometrium, tissue for study never should be obtained, either by instruments designed for office purposes or by dilatation and curettage, until the normal period of activity of these hormones on the endometrium has passed. For example, the information desired from examination of this tissue will not be obtained if specimens are removed from the uterus in the first half of the menstrual cycle (proliferative phase) regardless of whether the cycle is normal or abnormal. Normally, regenerative phenomena will have reached completion about twenty-five days after onset of the last period of bleeding. If, therefore, a disturbance of the regenerative process, as manifested by a persistently proliferative type of endometrium, is found on the twenty-fifth day, when differentiation should be nearly complete, then the desired information has been obtained, namely, that there has been a failure of luteinization. Specimens for study therefore, always should be taken around the twenty-fifth day of the cycle, regardless of whether the cycle is considered normal or abnormal, that is, the specimen should be removed twenty-five or more days after onset of the last period of bleeding.

Another significant feature of the problem lies in the fact that often, in examination of removed tissue, a study mistakenly is made of the basal layers of the endometrium. This will not afford information of value since the basal layers remain the same throughout the cycle. Therefore, the section of tissue studied always should contain the surface epithelium for it is from this portion of the tissue that the regenerative process is carried on. If the procedures mentioned are followed, often it is possible to determine the clinical syndromes associated with certain endometrial patterns. For exam-

ple, Randall and Herrell recently reviewed 278 cases of ovarian dysfunction in which cystic changes occurred in the endometrium. Classifying these tissues on the basis of the regenerative phases mentioned, they found that the greater the tendency toward differentiation, which is a function of the corpus luteum, the smaller the tendency toward bleeding dysfunction, while the tendency is greatest toward sterility. On the other hand, when these cystic changes were associated with arrestment of the regenerative process in the proliferative phase of the cycle (corpus luteum deficiency), the tendency was greatest toward bleeding dysfunction and to a lesser degree toward sterility.

It is further interesting that study of this remarkable regenerating tissue has recently led to the observation that cancer of the endometrium nearly always is associated with a certain type of endometrial pattern, namely, a persistently proliferative type of endometrium which denotes the presence of the estrogenic principle but lack of the differentiating power of the luteinizing factor. Absence of any evidence of malignancy in the endometria of patients previously subjected to oophorectomy is somewhat startling. These observations seem pertinent in view of the growing evidence for the carcinogenic tendency for estrin and estrin-like preparations

WALLACE E. HERRELL

tissue into a functioning unit is directly dependent on the action of the product of the corpus luteum, progesterone. The recovery of progesterone from urine of women was delayed for a considerable period. The explanation of this lies in the fact that the product of the corpus luteum, unlike the product of the follicle (estrogen), is excreted as a changed compound to which has been given the name pregnandiol. To Venning and her associates is credited this excellent observation which has recently been confirmed by Wilson Randall, and Osterberg. Before isolation of this product it was possible, however, by observation of the endometrial histologic characteristics, to predict the almost exact time of appearance in the urine of this recently isolated material. The prediction, of course, was made by observing the changes in the histologic pattern of the endometrium which follow almost immediately the period of initial activity of the corpus luteum.

Endometrium is the only human tissue in which study of regeneration has been possible. Regeneration of endometrium, just as is true of regeneration of any tissue, follows a definite histologic course of events. From observations of this process have come the interpretation of abnormal ovarian activity in terms of what normally occurs in regeneration. The first half of the regenerative process (menstrual cycle) consists in active proliferation of the tissue and this proliferation is controlled entirely by the action of estrogen, the product of the normally functioning follicle. As has been stated, differentiation of the endometrium into a functioning tissue depends on the principle of the corpus luteum progesterone. It follows then, that irregularity in the functional balance of the ovarian hormones which control this process is followed by irregularity in the regenerative phenomena controlled by these hormones. This in turn, results in men-

strual dysfunction either bleeding amenorrhea or sterility. If, therefore, the intention is to learn something concerning the activity of these hormones on the endometrium, tissue for study never should be obtained, either by instruments designed for office purposes or by dilatation and curettage, until the normal period of activity of these hormones on the endometrium has passed. For example the information desired from examination of this tissue will not be obtained if specimens are removed from the uterus in the first half of the menstrual cycle (proliferative phase) regardless of whether the cycle is normal or abnormal. Normally regenerative phenomena will have reached completion about twenty five days after onset of the last period of bleeding. If therefore, a disturbance of the regenerative process, as manifested by a persistently proliferative type of endometrium, is found on the twenty fifth day, when differentiation should be nearly complete then the desired information has been obtained, namely, that there has been a failure of luteinization. Specimens for study therefore always should be taken around the twenty fifth day of the cycle regardless of whether the cycle is considered normal or abnormal, that is the specimen should be removed twenty five or more days after onset of the last period of bleeding.

Another significant feature of the problem lies in the fact that often in examination of removed tissue a study mistakenly is made of the basal layers of the endometrium. This will not afford information of value since the basal layers remain the same throughout the cycle. Therefore the section of tissue studied always should contain the surface epithelium for it is from this portion of the tissue that the regenerative process is carried on. If the procedures mentioned are followed often it is possible to determine the clinical syndromes associated with certain endometrial patterns. For exam-

the authors point out in favor of the operation of jejunoplasty for this complication of what may seem to be a perfectly performed anastomosis or resection can be appreciated easily. They believe that this procedure should reverse the mortality rate following this complication because it relieves the obstruction at the actual point of occurrence with the minimum amount of surgery and, at the same time, permits direct inspection of the gastric stoma.

GYNECOLOGISTS and obstetricians may derive pleasure in entering the old controversy over whether or not a *myomectomy* or a *hysterectomy* should be done when fibroids complicate pregnancy and the fetus is viable. HUBER, formerly of Chicago, now of Indianapolis, evaluates the merits of each procedure and outlines in detail the management that he advises after consideration of all the problems concerned. Likewise, you may be interested in the fact that Professor ZONDEK, for various reasons, which he explains, is now performing myomectomy even more frequently than was his custom in the past. His experiences and indications are enumerated in a very interesting fashion.

IN the past the Editors have subscribed to the commonly held theory that all students of medicine welcome the opportunity to study the life, work, and environment of the great contributors to their profession, particularly if these are offered in an attractive and easily readable form. Our experience has confirmed that belief.

Recently we have brought reproductions of fine engravings of well known portraits of outstanding

men in medicine to our readers. This effort has been based on the conception that a fine gallery of art would serve better if it were mobile, that is, if its fine works of art could be placed on exhibition at intervals in every larger city in the country. We have, as a matter of fact, tried to do more than this. Each of these reproductions can be removed from the Journal and framed or preserved in any manner our readers choose.

We intend to add to the group already published an engraving by Henry Cousins of an Andrew Morton painting of SAMUEL COOPER. The senior surgeon to the North London Hospital, Cooper was the Samuel Johnson of medical literature. Though of a different stamp, and written with a different object, his *Dictionary* was to surgery what Johnson's great work was to English literature.

Sir Thomas Lawrence was a great artist and a Turner engraving of his magnificent portrait of Sir HENRY HALFORD, we think will please you. Physician to four successive sovereigns of England—George III, George IV, William IV, and Queen Victoria—he may be the one who long ago expressed the reason for the present interest of the laity in the life of doctors, when he said: "The conduct of a physician on whom is fixed the only hope of saving life, and on whom the dying look often rests, before the eye is closed forever, may fairly be thought interesting to every hearer."

The Editors hope that you will find these subjects which are to be discussed in forthcoming issues of SURGERY, GYNECOLOGY AND OBSTETRICS interesting and that these beautiful portraits will afford you pleasure.

ACROSS THE EDITORIAL DESK

IT is given to few surgeons to enunciate *principles of surgical treatment* but Philibert Joseph Roux who spent the active years of his surgical life in the Hotel Dieu in Paris where he lived from 1780-1854, stated such a principle which has become a law. In substance he said that functional pressure permits the formation of bony callus but tension or shearing forces inhibit the formation of callus and stimulate the production of fibrous connective tissue. Almost 100 years later, Pauwel described the reclamation method of the physiological reconstruction of non united fractures of the neck of the femur and his idea is based entirely upon the law enunciated by this same Roux. KARFIOL of San Francisco uses Pauwel's method and describes the advantages not found in other procedures. Of course there are few subjects about which there is so much discussion and in the treatment of which there are so many different methods as fractures of the neck of the femur.

PERHAPS you will not be in agreement with Karfiol's conclusions and prefer one of the many other methods in common usage. For example LEXDIG, of St. Louis, discusses the *treatment of fractures of the neck of the femur* and gives the results following the use of the Smith Peterson nail in a group of 75 patients treated during 1937.

SURGEONS of an older generation learned from many bitter experiences with children suffering from diphtheria just how to perform a tracheotomy but the introduction of antitoxin and the decrease in the number of cases of diphtheria have made the emergency operation of tracheotomy a rare one. Many of the younger generation of surgeons have probably never seen the operation, much less performed it. Mr. CANNON of London describes in detail just how to perform the unhurried, planned operation of tracheotomy so that the surgeon may well be acquainted with the procedure when circumstances demand a hurried operation.

THE moot question of just how much thyroid gland should be removed in a patient with hyperthyroidism is one which must be judged by every surgeon interested in *thyroid surgery*. CATTELL and PERLIN of the Lahey Clinic present

evidence which suggests that the pre-operative blood iodine level may be used as an index to determine the amount of gland tissue to be removed. Thus, an attempt is made to remove the question from one of personal judgment and place it upon a more scientific factual basis.

THE popularization of the use of *continuous suction applied to the indwelling duodenal tube* by Wangenstein and his associates at the University of Minnesota has led to rather widespread discussion of how long is required for dechlorination to do harm incident to the aspiration of the gastroduodenal secretions, how much fluid and what kind of fluid should be given and how the loss of fluid and sodium chloride can be estimated quickly and practically. PAINE from the surgical department of the University of Minnesota discusses this question and suggests two practical clinical methods for the quantitative estimation of the chlorides in the urine.

SURGEONS gynecologists, and obstetricians are all interested in any suggestion that makes *blood transfusion* simple, efficient and rapid. Some institutions have found the answer in the employment of a transfusion team. Others use blood banks. Professor A. HUSTIN and Dr. A. DUMONT, of Brussels describe a method which they use in transfusing citrated blood. Perhaps the reader will like his own method much better but he may get some suggestions for improvement from Professor Hustin's article.

THERE have been many modifications of the basic operation for gastrostomy and perhaps each surgeon has evolved his own method and technique, but we believe that our readers will be interested in the well illustrated method for an *aseptic double cal ed tubogastronomy* described by GLASSMAN and based upon work done in the anatomical and surgical departments of the University of Illinois. This should be particularly interesting to the younger surgeon who may not have had a considerable experience with the operation of gastrostomy. This is also true of the beautifully illustrated article by HOAG and SAUNDERS which describes a jejunoplasty for the relief of obstruction following gastro-enterostomy or subtotal resection of the stomach. The advantages which

The postgraduate student will find a ready and helpful guide to the problems of otology and the undergraduate and the general practitioner will find a useful consultant and aid to diagnosis and treatment of diseases of the ear

Twenty-six chapters and over four hundred pages with fifty illustrations comprise the text

JOHN F DELPH

THE *Outline of Roentgen Diagnosis*¹ represents a revision and expansion of the lecture notes used by the author in the teaching of roentgenology. As the title indicates and as the author states in the preface, this book is not a reference work but rather a synopsis of a very extensive subject. It goes without saying that it would be impossible to discuss and illustrate in detail the many uncommon conditions or to elaborate upon the rarer manifestations of the common diseases in a text of this type. The subject matter is dealt with in an orderly and concise manner and is a tribute to the author's experience in teaching. The indications, possibilities, and limitations of a roentgen study in each disease process are stressed throughout the text.

The book has been made up in two formats. One includes a pictorial atlas of 254 illustrations and reproductions of roentgenograms while in the other, suitable for teaching, the atlas section has been omitted. Although the atlas appears at the end of the volume, there are numerous references and cross references in the text to this section. The reproductions of roentgenograms are excellent and wisely chosen. Line drawings are utilized rather extensively and in most instances illustrate the lesion very well, but in others it would seem that reproductions might have been used to better advantage. This is not, however, a major fault. In illustrating many lesions the author has very wisely used line drawings rather than roentgenograms which often fail to reproduce well enough to demonstrate clearly the lesion under consideration. The unique drawings by Jean E. Hirsch illustrating the diseases of bones and joints are worthy of note. All illustrations are reproduced in the negative.

The subject matter has been divided into the following sections: general principles of roentgen diagnosis, bones and joints, diseases of the spine and spinal cord, skull and its contents, thorax, digestive tract, gall bladder, abdomen, urinary tract, female generative organs, and miscellaneous. All of the common disease processes falling under these various headings are adequately discussed.

This volume should be of interest to teachers of roentgenology. The author's orderly and concise manner of presenting the whole subject makes the book ideal for class room work and as a text for graduate students. It is recommended to members of the medical profession as a valuable addition to their library.

EARL E. BARTH

¹OUTLINE OF ROENTGEN DIAGNOSIS. AN ORIENTATION IN THE BASIC PRINCIPLES OF DIAGNOSIS BY THE ROENTGEN METHOD. By Leo G. Ruker, B.S., M.B., M.D. Atlas and student editions. Philadelphia, London, Montreal and New York. J. B. Lippincott Co., 1938.

THE third edition of *A Textbook of Gynecology*² by Arthur Hale Curtis, contains eight new chapters on anatomy, physiology, and the endocrine glands, which were not discussed formally in the two previous editions. The subject matter has been entirely rewritten and is based on the author's own experience combined with carefully selected excerpts from the current literature.

The chapter on anatomy is exceedingly timely because it is presented from the gynecologic standpoint and represents new and original work in dissection of the cadaver as well as in the operating room, coupled with Dr. Curtis' wide experience in this field. The drawings are unique in that they are original and made from dissections.

The discussion of organotherapy is excellent. The author's statement that "the average clinician is endocrine conscious and has endocrine panic," is very apt. Without camouflage, he presents the various gynecological disorders, which, in the past few years, have been treated with good, bad, and indifferent results, and he indicates clearly the few ailments successfully handled at the present time with the various preparations now available.

Descriptions of the more common gynecological operative procedures are included and they are clear, thorough and well chosen, as well as, accompanied by unusually fine illustrations. The importance of pre-operative and postoperative care is stressed and the management of various complications included. The indications and contra-indications for radiotherapy are ably discussed and the use of sulfanilamide in various pelvic disorders is described.

This is a book of 603 pages and 318 illustrations; it covers in a concise, direct manner the whole field of gynecology, and for this reason is ideal for the student and general practitioner, it also is a valuable addition to the gynecologist's library.

JAMES C. MASSON

THE English translation of *The Vitamins and Their Clinical Application*,³ published in Germany the early part of 1936, was made in the early part of 1938. The manual is an informative résumé of the history of vitamins and the progress made in vitamin science during the few years previous to 1936.

A historical introduction is presented on each of the known vitamins. There then follows discussions on the chemistry (giving chemical formulas), determination, occurrence, manifestation of the vitamin deficiency, and the daily requirements in man. Attention is called to some of the reliable commercial preparations, with dosage, that may be used in treating vitamin deficiencies. The last three chapters are discussions on vitamins and human nutrition, daily vitamin requirements for man, and the antagonism of vitamins and its importance in vitamin therapy.

³THE VITAMINS AND THEIR CLINICAL APPLICATION. By Prof. Dr. W. Stepp, Doz. Dr. Kuehnau, and Dr. H. Schroeder. Translated by Herman A. H. Bouman, M.D. Milwaukee, Wis. The Vitamin Products Co., 1938.

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

THE authors of *Surface and Radiological Anatomy*¹ have commendably ventured to move beyond the customarily accepted range of treatises on surface anatomy. To the established methods of physical examination they have added those of radiology thus a dependable old method is modernized and vitalized by the addition of a new.

Illustrations are bountifully used through their excellent character, the authors have succeeded in co-ordinating radiographic anatomy with those external bodily features discoverable by sight and touch and these in turn with the details of deeper morphology with which the reader has become familiar in the dissection laboratory. Pictorially the student and the practitioner is furnished with a superb record of human structure accruing from three branches of anatomic science by means of which he is enabled to view the body as if it were a transparency transfer to its external regions the sites of osseous visceral vascular and nervous elements.

Each part of the human body is treated on a systematic plan. To select an example the superficial muscles of the extremities are discussed as palpable structures in relation to surface outlines these relations being rendered graphic by the employment of parallel illustrations their margins are described in reference to bony prominences to fossae produced by their elevations, and to deeper structures discoverable by palpation the important contents of the fossae are in turn described as to position and course within the space. The discussion then proceeds to movements possible at the particular joint the movement of individual bones being illustrated by photographs of a living subject upon which the outlines of the bones have been projected radiographs presented in serial order illustrate the changing interrelationship of bones which compose the joint.

In the chapters on the thorax and the abdomen the reader is carried successively through a discussion of surface landmarks of parietal musculature and of contained viscera.

There is an uncommonly good discussion of the principles of radiological examination supplemented by drawings to illustrate the special significance and anatomy of oblique views. Where radiography may profitably be supplemented by direct examination of the living organ gastroscopy cystoscopy, et

cetera are added to the authors abundant list of features.

During the years in which the reviewer has employed radiography as an adjunct to the regular course in dissection the need for such a textbook has been constantly felt. Altogether, this is a remarkable work. So inclusive is the content so logical the arrangement of subject matter that it may safely be recommended to the medical student in any period of his training and to the practitioner.

BARRY ANSON

AN extremely well compiled review of the literature in regard to sulfanilamide therapy of bacterial infections is presented by Mellon Gross and Cooper.² The early history of the drugs is of special interest from the standpoint of a therapeutic applicability of the azo compounds.

There are chapters on the pharmacology chemistry and chemotherapeutic effects of sulfanilamide. In these chapters the authors have very thoroughly reviewed the literature including all of the important references in regard to the experimental uses of the drug. The chapters on the experiments *in vitro* and *in vivo* should be read by anybody who is using sulfanilamide compounds. Other high points of interest are the effects reported in infections other than the streptococcus group namely meningitis gonococcus and pneumococcus infections.

The reviewer would certainly like to commend the authors for compilation of so much valuable data concerning a drug of which so little is generally known. This book at least begins to fill a large gap in our knowledge of chemotherapy.

GILBERT H. MARQUARDT

THE book *Practical Otolology*³ by Dr. Levine is written from thirty years experience of teaching graduate students and is essentially a compilation of a series of lectures given during that period. It is not a textbook in the usual sense as all controversial subjects and long drawn out descriptions are left out the author devotes himself to short concise descriptions of the subject matter.

The book has been entirely overhauled and re-written with new chapters on the latest work on petrositis and aviator's ear. There is a valuable formulary accompanying each chapter on treatment.

SULFANILAMIDE THERAPY OF BACTERIAL INFECTIONS WITH SPECIAL REFERENCE TO DISEASE CAUSE BY HEMOLYTIC STREPTOCOCCI, PNEUMOCOCCI, MENINGOCOCCI AND GONOCOCCI. By Ralph R. Mellon M.D. Dr. P. H. D. S. (H.) Fr. 1 Gross M.D. & d. Fr. 4 B. Coopers M.D. Springfield Ill. & d. H. H. more M.D. Chicago Ill. 1935
³ PRACTICAL OTOLLOGY. By Morris Levine M.D. F.I.C.S. 2d rev. ed. Philadelphia L. & F. 1935

¹ SURFACE AND RADIOLOGICAL ANATOMY. FOR STUDENTS AND GENERAL PRACTITIONERS. By Arthur B. Appleton M.A. M.D. (Cambr.) Will. M. J. Hamlin M.D. B.Ch. (B. H.) D.Sc. (Gl. s.) F.R.S.E. & d. Ivan C. C. Tech. pe. off. M.A. M.D. B.Ch. (Ca. tab.) D.M.R.E. Baltimore W.D. H. Wood & Co. 1933

This manual offers a clear presentation of the subject of vitamins and their practical application to the human being both in health and disease. However the reader must bear in mind the many new discoveries that have been made in vitamin science during

the past 3 years. The vitamin chart with detailed bibliography (found in the appendix) offered by the English editors is valuable for those who desire to make a special study of the vitamins. References on this chart are only up to 1937. C. J. BARBOREA

NUMBER 2A

HERNIATION THROUGH THE DIAPHRAGM

JOHN J. MORTON, M.D., F.A.C.S., Rochester, New York

HERNIATION through the diaphragm occurs more frequently than is generally recognized by physicians. If the practitioner will suspect it as a cause for unexplained epigastric or lower thoracic complaints, and if he will follow up by the proper examinations, he will be gratified by the number of diagnoses to his credit.

In its development from the septum transversum and its accession of sternal, costal, and lumbar musculature, the diaphragm offers many opportunities for imperfect fusion of these elements. Thus, there may be abnormal openings through it from a failure in appearance, in timing, or in the fusion of the separate components. This is likely to take place peripherally in the posterolateral areas between the costal and lumbar regions, leaving the Bochdalek's foramina, or in the parasternal region, the so called foramina of Morgagni (the *fente de Larrey* of the French writers). Added to this is the fact that the stomach also forms in the thoracic region and has to descend, rotate, and assume its adult position, all in proper timing relationship to the formation of the diaphragm. In consequence, there may be complete failure of the stomach to get below the diaphragm (the thoracic stomach), or partial descent with varying degrees of

thoracic and abdominal gastric portions, or small remnants of the cardiac end of the stomach may be nipped off near the esophageal hiatus, or there may be simply an imperfectly formed area near the esophagus, a potentially weak spot which may determine the site of a future herniation if given the proper conditions.

TYPES OF HERNIAS

In the literature, herniations through the diaphragm are classified as true or false, depending on the presence or absence of a hernial sac. They are also considered to be congenital, traumatic, or acquired. Any of these latter groups may or may not have a true sac present. The classification is mainly one of convenience. It would be equally proper to consider some of these protrusions through the diaphragm as due to faulty fusion of the muscles, absence of portions of the diaphragm, imperfect descent of the stomach, or in case of trauma, internal eviscerations through the diaphragm.

I Congenital In the etiology of the congenital hernias, the trouble usually can be traced to the imperfect development of some portions of the diaphragm, or to the improper descent of the stomach and esophagus through the diaphragm. The congenital herniations may give symptoms immediately after birth. In such a case, there is cyanosis, dyspnea, and embarrassment of the circulation. Certain positions make the condition worse while

From the Department of Surgery, the University of Rochester School of Medicine and Dentistry.

Howard C. Haffigian

PRESIDENT 1938 1939

days later of bronchopneumonia, myocarditis, prostatic hypertrophy, hydro-ureter and hydronephrosis

Congenital herniations through the parasternal area may give precordial pain, a feeling of tightness in the chest, retrosternal pressure, or palpitation. Strangulation of the bowel with its accompanying symptoms has occurred in 10 per cent of the reported cases of retrosternal diaphragmatic hernia (12)

CASE 7 E M, No 47362, a male, aged 22 years, was admitted to Strong Memorial Hospital on May 10, 1931. As long as he could remember he had had a constant, dull pain in the left chest medial to nipple and low, this grew worse with exercise and on deep inspiration. He traced his trouble to an injury received 8 years previously. He had fallen down stairs with a bicycle, the pedal puncturing the left abdominal wall, but the peritoneum was not opened. Examination showed the left side of lower chest to be slightly more prominent than the right, and a circular scar on the left epigastrium. Otherwise he was normal. The roentgenogram showed the transverse colon through the diaphragm (Figs 5 and 6). Operation was performed with a left phrenic block. There was a well-formed sac with the transverse colon adherent, which was dissected free and the diaphragm closed. The patient is now well.

The diagnosis of congenital herniation through the diaphragm is exceedingly difficult to make at times. The symptoms caused by these hernias have been detailed in the preceding paragraphs. The signs given by herniated viscera into the thoracic cavity are variable and difficult to evaluate. The combinations of air, fluid and solid material produce many peculiar signs. The congenital and traumatic types are likely to confuse the physician, as there are usually more contents in the thoracic cage in these varieties.

In the last analysis, the diagnosis is possible only by accurate roentgenograms which show the position of the organs in relation to the diaphragm. It may be necessary to give barium by mouth to outline the organs involved accurately. When the large bowel is in the herniation, a barium enema will demonstrate the portion of the colon which is participating.

The prognosis depends upon the size of the opening through the diaphragm and the character of the herniated viscera. When the vital capacity is much reduced, the infant may not survive the early days. As he becomes more

Fig 1 Case 3 This is the usual picture of a herniation of the small and large intestine through the left posterolateral Bochdalek's foramen

accommodated to the compression of the lungs he may compensate for it by expansion of the opposite side. The pressure on the mediastinum may cause a considerable shift of its contents. In theory it is possible that the heart and great vessels may be embarrassed by the abnormal mechanical pressure. When once the infant passes the early critical period, he may not show any evidence of trouble except perhaps in general underdevelopment and in distortion of the thoracic cage. These have been noted frequently by keen clinical observers. There is always the danger of potential obstruction and strangulation, although in my experience this is far less frequent than has been reported by others. Strangulations in herniations through the foramen of Morgagni have been reported in 10 per cent of cases (12).

The treatment depends upon the type of the lesion and the nature of the symptoms it produces. The congenital types should probably be operated upon at a favorable time when possible, and under stress conditions when necessary. The most common postero-

others relieve it. There may be alarming and critical attacks alleviated only by administration of oxygen. These patients may require surgery although the risk is very great.

CASE 1. D. C., No. 96068, a female, was admitted to Strong Memorial Hospital December 1, 1934 at 5:30 p.m. At 6:00 a.m. December 2 she gave birth to a male infant after a normal delivery. The child was very cyanotic at birth but was resuscitated. Three attacks of extreme cyanosis and dyspnea occurred during the day. Breath sounds were very faint over the left chest where there was slight fullness anteriorly and laterally; there was cardiac dullness anteriorly on the right, the point of maximum impulse was in the fourth right intercostal space. The roentgenogram showed herniation through the diaphragm. When on the left side, cyanosis was less but several attacks necessitated the use of the oxygen tent. An exploration was performed on December 6 but it was impossible to return the organs from the chest by either the thoracic or the abdominal route. An oxygen tent was employed after operation but the infant died on December 8, 1934.

Some infants do not survive the first day.

CASE 2. B. B., No. 83262, a boy baby who died soon after birth. At postmortem examination a large opening was found posteriorly through the left diaphragm. The stomach, the small intestine and all of the large intestine down to the descending colon occupied the left thoracic cage. The mediastinum was shifted to the right. There was coarctation of the aorta and dilatation of the ductus arteriosus.

Other patients may adjust themselves to the changed relationships and be considered normal. Only later in life it may be noted that they are below the average development for their age and that an abnormality in the shape of the thorax exists. Such patients may present no symptoms referable to their herniation.

CASE 3. H. S., No. 85308, a boy aged 12 years in good health till September 14, 1933 was admitted to Strong Memorial Hospital on September 21, 1933 because of a respiratory infection followed by diabetes mellitus. Previous history revealed pneumonia at 2 years. Examination showed prominence of the anterior chest wall, region xiphoid dullness on percussion on left side from angle scapula to base forward to anterior axillary line, signs of fluid distended breath sounds and vocal fremitus. Diagnosis showed resolving pneumonia, thickened pleura and pleural effusion. Roentgenographic diagnosis revealed consolidation or pleural effusion. Gurgling sounds heard suggested bowel invagination. A gastro-intestinal series showed herniation of the large and small bowel through the diaphragm (Fig. 1).

There may be very trivial upsets in digestion.

CASE 4. R. F., No. 96751, a boy aged 5 years was admitted to Strong Memorial Hospital January 6, 1933. There had been irregular vomiting for 2 years usually at night but no other complaint. Temperature was normal, pulse 100, respirations 20, white blood cells 6,000. The left thorax was more prominent than the right, in the left lung from mid scapula to base, vocal fremitus was decreased and percussion note flat but there were no rales. Heart sounds were heard best to the right, no shift of heart was made out. There were prominent veins over the upper abdomen, and numerous walnut sized masses on both sides of the abdomen. Various diagnoses of pleural effusion, unresolved pneumonia, tuberculosis, lung abscess and bronchiectasis were considered by attending physicians (Fig. 2). Signs and symptoms did not fit any of these diagnoses. The possibility of hernia on was finally suggested and a gastro-intestinal series made the diagnosis sure. Operation was performed and the organs were restored to the abdominal cavity. The posterior defect in the diaphragm is demonstrated in Figure 3. The wound was packed to form adhesions and the result was good.

Some patients may go through life with very few complaints (Cases 5 and 6).

CASE 5. C. F., No. 106886, a man aged 61 years, was admitted to Rochester Municipal Hospital on September 14, 1935 with a fractured left hip. Examination showed the patient to be semicomatose, the entire chest full of rales, complete fracture of the left femoral neck, arteriosclerosis and auricular fibrillation. He died 17 1/4 hours. Postmortem examination revealed bronchopneumonia, pulmonary fat embolism, cirrhosis of the liver and other signs of degeneration due to age. In addition the right diaphragm showed a bulging into the right cavity behind a band of fibrous tissue which extended from the spine to the anterolateral chest wall. This diaphragmatic herniation contained the right lobe of the liver and lateral to it some small bowel loop.

CASE 6. A. H., No. 40178, a male aged 70 years was admitted to Strong Memorial Hospital on October 19, 1930. He had intermittent pain in the epigastrium for 2 years, a loss in weight of 30 pounds, icteric emaciation, hypertension, bladder retention, benign prostatic hypertrophy, cystitis, fever, white blood cell 18,000 to 32,000 and anemia. A gastro-intestinal series showed a mass in the pyloric region, and herniation of the transverse colon through the diaphragm (Fig. 4). Under scopolamine and local anesthesia the abdomen was explored. Chronic cholelithiasis, cirrhosis and chronic pancreatitis were found and a cholecystoduodenostomy was performed. The patient died 14

Fig 5 Case 7 Herniation of transverse colon through left parasternal defect (Morgagni's foramen)

Fig 6 Case 7 Lateral view indicating the constriction of the bowel at the sac opening

known by acute dilatation of the abnormally situated organs. If not relieved relatively soon, it may lead to strangulation.

CASE 8 R C, No 114648, a male, aged 32 years, was admitted to the Strong Memorial Hospital on May 4, 1936. In an auto accident 3 days previously he suffered a fracture of the left ilium, right clavicle, and herniation of the stomach through the left diaphragm. The left chest lagged on inspiration. Percussion note was tympanitic anteriorly from the third left interspace to the ninth left interspace, there were also splashing and gurgling sounds. There were no breath sounds, vocal fremitus was decreased, there was an absence of tactile fremitus, and the heart was displaced to the right. The electrocardiogram showed auriculoventricular heart block and myocardial damage, Wassermann reaction was 4 plus. Operation was performed with a phrenic nerve block and the rent in the diaphragm was repaired. The tear was to the right of the esophageal hiatus. The cardia and the pylorus were side by side at the level of the diaphragm. Omentum and splenic flexure were drawn up into the chest. It was necessary to enlarge the rent to free the organs. The stomach was markedly dilated. Exposure was obtained by a costoplastic procedure. A stormy convalescence followed, but the patient was discharged in good condition on August 19, 1936 (Fig 7).

In other accidents the herniation symptoms are completely submerged. It may be months or years before the condition is suspected or

makes itself known. There may then follow symptoms referable to the occlusion of the viscera which have herniated through the tear in the diaphragm. There will also be a gradual compression of the lung on the involved side with a diminution in the vital capacity. In Case 9 this amounted to 28 per cent. The heart is slowly displaced toward the opposite side of the chest by pressure on the mediastinum. This may lead to cardiac disturbance by angulation and distortion of its vascular connections.

CASE 9 F M, No 113380, a woman, aged 33 years, was admitted to Strong Memorial Hospital on May 18, 1936. She was in an auto accident August 29, 1935, and suffered a fracture of 6 ribs on the left side. She remained in the hospital 1 month and another month with relatives. On her return home, she suffered pain in the back, shortness of breath, and sharp pain while eating. A roentgenogram revealed herniation of the stomach, transverse colon, splenic flexure into the chest, and a heart displaced to the right. Examination showed angulation of the second to the eighth ribs on the left, posteriorly, percussion note was dull with moderate tympany over the left thorax, laterally and posteriorly, and

Fig 2 Case 4 A roentgenogram such as this is quite confusing for interpretation

lateral variety through the foramen of Bochdalek can be approached either by the thoracic or abdominal route or a combination of the two. A lateral thoracic incision between the

Fig 4 Case 6 Bilateral herniation through the parasternal foramina (Morgagni)

ninth and tenth ribs will usually expose the defect and allow easy closure by removal of an overlying rib, if necessary, for relaxation. This is not so easily done from the abdominal side. The parasternal types should have a preliminary phrenic block and closure from the abdominal route. In those unusual congenital herniations through the central tendinous area or in the paraesophageal region, the operations to be described for the traumatic and acquired types should be successful.

2 Traumatic Traumatic herniations through the diaphragm are the results of tears through the muscular or tendinous portions with the escape of abdominal viscera into the thorax, aided and abetted by the differences of pressure between these two cavities. The trauma necessary to cause a tear in the diaphragm almost always represents a severe injury of some kind to the lower thorax or upper abdomen. Such injuries occur from anything which causes violent doubling or torsion of the body such as auto accidents, falls, machinery accidents, gunshot wounds, stab wounds or heavy lifting. Traumatic herniation has occurred at childbirth, or from the rupture of an abscess through the diaphragm from either side—a subphrenic abscess or empyema.

Often times the symptoms of traumatic herniations are masked by the shock incident to the severe accompanying trauma. In some instances however the condition makes itself

Fig 3 This drawing represents the defects in the diaphragm and the position of the organs in the thoracic cavity in Case 4

Fig 9 Case 9 The large intestine has also herniated into the thorax

Fig 10 Drawing showing the traumatic defect in the diaphragm and the condition found at operation in Case 9

such as gastritis, gastric ulcer, gastric cancer, pylorospasm, duodenal ulcer, cholecystitis, and cholelithiasis, or the symptoms may be difficult to differentiate from esophageal conditions such as cardiospasm, diverticulum, benign stricture, or carcinoma of the esophagus; or finally, there is a chance to confuse these symptoms with those of some cardiac conditions such as angina pectoris, coronary occlusion, and myocardial damage. The gastro-intestinal symptoms include epigastric pain, and distress or fullness, which may or may not be relieved by soda, food, rest, belching, vomiting, or change of position. Some patients complain of this pain especially after large meals, or shortly after retiring at night. Sometimes the pain is accentuated by deep breathing or by leaning over; and often it is relieved by assuming the erect posture. The pain frequently radiates to the angle of the scapula. Belching and gas on the stomach, nausea and vomiting are relatively common. The presence of blood in the vomitus or stool, accompanied by dizziness, weakness, and severe anemia, often lead to suspicion of a

bleeding ulcer. These patients occasionally have upsets in their bowel habits, diarrhea or constipation. They often develop fear of eating and in consequence may lose weight. This causes the physician to consider a diagnosis of cancer. The esophageal symptoms include the following: difficulty in swallowing, increasing inability to retain food, regurgitation, a feeling of pressure in the retrosternal region, and loss of weight and strength. The cardio-respiratory symptoms are heart pain and palpitation, substernal pain and pressure, radiation of pain to the arms, shortness of breath, and fear of impending death. Diaphragmatic spasm sometimes causes phrenic pain and hiccoughs.

As more of the stomach becomes involved in the herniation, the symptoms may intensify, become more frequent and are not relieved easily. When incarceration and fixation occur, the symptoms may become continuous de-

Fig 7 Case 8 Traumatic rupture of the left dome of the diaphragm The stomach has herniated into the left thoracic cavity It is obstructed and operation is imperative Catheter shows in much dilated stomach

Fig 8 Case 9 Traumatic rupture of the left diaphragm Gastro intestinal series shows herniation of stomach into left thoracic cavity

breath sounds were distant An operation was performed by means of a phrenic block The stomach and colon were restored to the peritoneal cavity and the torn diaphragm was repaired Convalescence was uneventful There has been no trouble since operation Vital capacity before operation was 2.6 liters, after operation 3.75 liters Total capacity before operation was 3.50 liters after operation 5.25 liters The vital capacity was reduced 28 per cent Carbon dioxide and oxygen of the arterial blood before operation were normal The dyspnea was due to reduced vital capacity and pulmonary reserve (Figs 8, 9, 10)

Herniations of the traumatic type can be handled from the thoracic or from the abdominal approach Surgeons who do a great deal of thoracic surgery usually prefer the thoracic operation The claim is made that it is easier to work from the upper side of a tear with everything below you than it is to work on the under side with everything above Others choose the abdominal operation as it is easier in their hands There should be no quarrel regarding the relative merits of these methods The well equipped surgeon should be prepared to operate by either or both approaches if necessary The tear in the central

tendon should be freshened and approximated accurately Temporary paralysis of the diaphragm by phrenic nerve crush may be of assistance although it is not always a necessity If the approach is through the thorax this can be carried out or not as needed

3 *Acquired* Hernias of the acquired type more nearly correspond to hernias of other portions of the abdominal cavity These acquired diaphragmatic hernias develop at areas of weakness They often require years in their formation An unusual strain may quickly accentuate them They are fostered by upward pressure of the intra abdominal viscera, by aspiration and the vacuum suction power of the thoracic cavity, by a traction cone caused by esophageal muscular contraction, and by the insinuation of fat tabs which act as entering wedges to dilate the small openings Their para esophageal situation is quite characteristic

The symptoms of the acquired esophageal hiatus are the most interesting These herniations give symptoms which may closely mimic those of gastro intestinal conditions

Fig 9 Case 9 The large intestine has also herniated into the thorax

such as gastritis, gastric ulcer, gastric cancer, pylorospasm, duodenal ulcer, cholecystitis, and cholelithiasis, or the symptoms may be difficult to differentiate from esophageal conditions such as cardiospasm, diverticulum, benign stricture, or carcinoma of the esophagus; or finally, there is a chance to confuse these symptoms with those of some cardiac conditions such as angina pectoris, coronary occlusion, and myocardial damage. The gastro-intestinal symptoms include epigastric pain, and distress or fullness, which may or may not be relieved by soda, food, rest, belching, vomiting, or change of position. Fig. 11. Case 13. Herniation of a portion of the fundus through the para-esophageal hiatus. There is associated esophagospasm as shown by the string like lower esophagus. This area relaxed at times and filled normally.

Fig. 12. Case 14. A large amount of the fundus has herniated through the diaphragm at the para-esophageal hiatus. The ruga can be seen traversing the constricting ed, e of the sac.

manding surgical intervention for relief. The bleeding is a sign of significance, indicating congestion or thrombosis of vessels about the constricting ring of the opening with erosion of the mucous membrane and even ulceration in a number of cases.

Many patients go through their lives with only minor trouble, easily controlled by medical treatment. But when the symptoms become continuous and intense, surgery must be seriously considered.

The following case histories illustrate the variation in the symptomatology in esophageal hiatus herniations. Cases 10 and 11 demonstrate the gastro intestinal symptomatology.

CASE 10. C. C., No 105474, a woman aged 47 years was admitted for the fourth time to Strong Memorial Hospital on June 21, 1937. Previous admissions were for acute gastro enteritis, suspected gastro intestinal malignancy, secondary anemia and achlorhydria. Hernia through the diaphragm at the esophageal hiatus finally was demonstrated. In 1926 a laparotomy was performed because a diseased gall bladder was suspected. This was not found and it was thought that a duodenal ulcer was present. Posterior gastro enterostomy was done at that time. Epigastric hunger pain 3 hours after eating is now relieved by food and soda. Lower thoracic pain is relieved by recumbency. She obtained relief under medical treatment. She gave this up and during 5 months all symptoms grew worse with dyspnea, hypochromic anemia and achlorhydria and she became sallow. The patient improved under medical treatment.

CASE 11. L. F., No 122726, a male aged 72 years was admitted to Rochester Municipal Hospital on December 21, 1936. Nine months previously he suddenly lost his appetite because eating caused substernal pain which radiated to both lower quadrants. There were associated nausea and vomiting. Roentgenograms at that time were reported as cancer of the lower esophagus or cardiac end of the stomach. There was a loss of 10 pounds in weight and anemia. Examination showed the patient to be emaciated, pallid, with an enlarged prostate and secondary anemia. The gastro intestinal series revealed diaphragmatic hernia with cardiospasm, doubtful lesion at the cardiac end of the stomach. There was achlorhydria but there was no blood in the gastric secretion. The general opinion of consultants was against carcinoma. The patient was discharged for medical care.

Case 12 illustrates the difficulty in differentiating one of these hernias from a cardiac condition.

CASE 12. No 119025, a male aged 48 years was admitted to Strong Memorial Hospital on September 8, 1936. He had had a pressure sensation in the chest for 5 years which he thought to be dyspepsia. For 1 year he suffered with palpitation and dyspnea which he relieved by cutting down on cigarettes 30 a day. Three weeks previous to admission he experienced a severe sensation of pressure in the chest with sharp pains in both arms. He felt as if chest and arms were gripped in a vise and this lasted 6 minutes. He suffered a similar attack the same evening. In Boston the electrocardiogram was interpreted as coronary disease. The patient was put on heart drugs. Examination showed a heart slightly enlarged with some extra systoles; the electrocardiogram showed extra ventricular systoles and a sino auricular block. The gastro intestinal series revealed that the fundus slid laterally and

Fig. 13. Case 15. Large herniation with marked symptoms. Fluid retention and fluid level well demonstrated. Diaphragm shadows show through breast shadows.

anteriorly through a defect in the diaphragm on deep inspiration. The patient was discharged to his physician. Repeated attacks of discomfort after meals were found to be associated more with the hernia. He can now take strenuous exercise with a regular heart. The patient is quiescent under medical treatment but if trouble recurs surgery is to be performed.

Cases 10, 11, and 12 showed large herniations of the cardiac end of the stomach through the esophageal hiatus similar to that in Figure 20. In Case 13 the esophageal symptoms were in the foreground.

CASE 13. E.B., No. 115330, a woman, aged 74 years, was admitted to Strong Memorial Hospital on May 22, 1936. For 2 to 3 years food had stuck in her throat and would not go down especially solid food and cold drinks. She could swallow hot drinks. Her distress increased food went to a point in the center of breast bone stopped and hurt quite badly. She suffered shortness of breath, belched and regurgitated. She could usually raise a mouthful of slime in the morning. For many years the patient suffered with gas on stomach and belching but no pain and no heart burn. She was afraid to eat and had lost 10 to 15 pounds in 5 months. Examination showed her to be alert, well nourished, and normal for her age. The impression was cardiospasm, but the gastro-intestinal series revealed herniation, a part of the stomach was through the diaphragm and there was an angulation of the esophagus. Symptoms continued but the patient wanted nothing done. Phrenic nerve crush has been advised (Fig. 11).

The 3 following cases are examples of incarceration and fixation in the hernial sac. Surgery is advisable in these cases to get relief. The patients are so uncomfortable that they accept operation readily.

Fig. 14. Case 16. Tracing of roentgenogram showing large portion of stomach herniated through para-esophageal opening. Esophagus demonstrated to be of normal length. Operation possible.

CASE 11. E.B. No. 58015, a woman, aged 39 years, was admitted to Strong Memorial Hospital on July 6, 1932. She began to have attacks of sharp pain in the lower left chest 12 years previously but the cause was undetermined. The patient showed signs of hematemesis 1 years before. Gastric ulcer was diagnosed and strict diet gave no relief. The pains grew worse and during the last 5 weeks she had endured frequent and severe epigastric pain. For 1 week there had been constant pain, slight fever, hiccoughs and very troublesome pain radiating down the inner side of the left arm. Dyspnea had been present on exertion for 8 years. Examination showed the patient to be well developed and nourished; the general physical examination was normal. The gastro-intestinal series revealed a large herniation of the stomach through the diaphragm. She was operated upon and the herniation admitted 3 fingers easily. The spleen, adherent to the sac, was torn in freeing it. Severe bleeding followed which was controlled by suturing the spleen. The herniation was packed after partial closure. There was some shock and a slow recovery. Since operation the patient has gained 20 pounds in weight, and there is only an occasional mild discomfort in the left, upper quadrant. She has developed arthritis of moderate severity (Fig. 12).

CASE 15. M.E., No. 74040, a female, aged 53 years, was admitted to Strong Memorial Hospital on April 13, 1933. One and one half years previous to admission she began to have epigastric pain, burning in character, radiating to left upper quadrant 1 to 2 hours after eating. It was relieved by soda and vomiting. She experienced freedom from pain for 1 to 2 week periods. Two weeks before admission, respiratory infection associated with epigastric pain, nausea and vomiting were present. Examination revealed an enlarged heart and hyper-

Fig 11 Case 13 Herniation of a portion of the fundus through the para esophageal hiatus. There is associated esophagospasm as shown by the string like lower esophagus. This area relaxed at times and filled normally.

manding surgical intervention for relief. The bleeding is a sign of significance, indicating congestion or thrombosis of vessels about the constricting ring of the opening, with erosion of the mucous membrane and even ulceration in a number of cases.

Many patients go through their lives with only minor trouble, easily controlled by medical treatment. But when the symptoms become continuous and intense, surgery must be seriously considered.

The following case histories illustrate the variation in the symptomatology in esophageal hiatus herniations. Cases 10 and 11 demonstrate the gastro intestinal symptomatology.

CASE 10 C. C. No 105474 a woman aged 47 years was admitted for the fourth time to Strong Memorial Hospital on June 21 1937. Previous admissions were for acute gastro enteritis suspected gastro intestinal malignancy secondary anemia and achlorhydria. Hernia through the diaphragm at the esophageal hiatus finally was demonstrated. In 1926 a laparotomy was performed because a diseased gall bladder was suspected. This was not found and it was thought that a duodenal ulcer was present. Posterior gastro enterostomy was done at that time. Epigastric hunger pain, 3 hours after eating is now relieved by food and soda. Lower thoracic pain is relieved by recumbency. She obtained relief under medical treatment. She gave this up and during 5 months all symptoms grew worse with dyspnea hypochromic anemia and achlorhydria and she became sallow. The patient improved under medical treatment.

Fig 12 Case 14 A large amount of the fundus has herniated through the diaphragm at the para-esophageal hiatus. The rugae can be seen traversing the constricting edge of the sac.

CASE 11 L. F. No 122726 a male aged 72 years was admitted to Rochester Municipal Hospital on December 21 1936. Nine months previously he suddenly lost his appetite because eating caused sub sternal pain which radiated to both lower quadrants. There were associated nausea and vomiting. Roent genograms at that time were reported as cancer of the lower esophagus or cardiac end of the stomach. There was a loss of 10 pounds in weight and anemia. Examination showed the patient to be emaciated pallid with an enlarged prostate, and secondary anemia. The gastro intestinal series revealed diaphragmatic hernia with cardiospasm, doubtful lesion at the cardiac end of the stomach. There was achlor hydria but there was no blood in the gastric secretion. The general opinion of consultants was against carcinoma. The patient was discharged for medical care.

Case 12 illustrates the difficulty in differentiating one of these hernias from a cardiac condition.

CASE 12 No 119025 a male aged 48 years was admitted to Strong Memorial Hospital on September 8 1936. He had had a pressure sensation in the chest for 5 years which he thought to be dyspepsia. For 1 year he suffered with palpitation and dyspnea which he relieved by cutting down on cigarettes 30 a day. Three weeks previous to admission he experienced a severe sensation of pressure in the chest with sharp pains in both arms. He felt as if chest and arms were gripped in a vise and this lasted 6 minutes. He suffered a similar attack the same evening. In Boston the electrocardiogram was interpreted as coronary disease. The patient was put on heart drugs. Examination showed a heart slightly enlarged with some extra systoles. The electrocardiogram showed extra ventricular systoles and a sino-auricular block. The gastro intestinal series revealed that the fundus slid laterally and

Fig 17 Case 48 The constricted area of the herniated portion of the stomach is well shown The fluid level shown in Figure 16 is in a subdiaphragmatic diverticulum of the greater curvature of the stomach

are a good many cases in which only a small knuckle of the fundus is demonstrated during the gastro-intestinal barium study (Fig 18) The 15 following cases serve to illustrate this type of patient The symptoms are often severe although the herniation is small In some cases the herniation undoubtedly was responsible for most of the symptoms, in some cases there were other pathological lesions associated, in some, the demonstration of the hernia was apparently only coincidental

Cases 18, 19, 20, 21, 22, 23, and 24 have a predominant gastro-intestinal history

CASE 18 L C, No 109266, a male, aged 80 years, was admitted to Strong Memorial Hospital on November 17, 1935 The patient gave a history of epigastric pain, belching, cramps with nausea and vomiting for 5 to 6 years Five days previous to admission diarrhea, melena, and pain occurred Examination revealed pallor, slight enlargement of the heart, umbilical hernia, liver 2 fingers breadth down, enlarged prostate, hypertension and arthritis His red blood cells were reduced to 125 red blood cells, hemoglobin 4.5 grams The patient was drowsy but there was a gradual improvement The gastro-in-

Fig 18 Case 49 Some small herniations can be demonstrated in the flat plate as extensions of the gas bubble above the diaphragm

testinal series revealed a small diaphragmatic hernia, 2 duodenal ulcers He had spells of bleeding Final improvement was brought about under medication

CASE 19 E McK, No 121043, a female, aged 70 years, was admitted to Strong Memorial Hospital on November 5, 1936 There had been insidious onset of general weakness, anorexia, and insomnia 6 months previously from which the patient recovered somewhat with bed rest Similar attacks occurred 2 months later with vague epigastric discomfort especially on bending over There was present

Fig 19 Case 50 A lateral view sometimes gives an accurate picture of the amount of herniated stomach and its relation to the diaphragm

Fig 15 Case 39 This roentgenogram shows a large herniation. Many of the cases have herniations of this size

Fig 16 Case 48 The roentgenogram shows the herniation of the stomach through the diaphragm. It resembles a cystic area in the lower left thorax. A fluid level is seen below the diaphragm on the left

tension. The gastro intestinal series showed a large herniation of the stomach through the diaphragm. An operation was performed in which stomach and spleen were returned to the abdominal cavity. There was no ulceration of the stomach and the diaphragm was repaired. Convalescence was uneventful. The patient has been asymptomatic to 1938 (Fig 13).

CASE 16 F S No 3725 a woman aged 64 years was admitted to Strong Memorial Hospital on November 3, 1926. Anemia and weakness occurred periodically for 14 years and the onset always followed fatigue. She had been in bed all summer previous to admission. Iron and rest usually were all that were necessary. There was no loss in weight and no gastro intestinal symptoms. Severe melena occurred 27 years before and there was occasional bleeding from the rectum since. Examination showed a stout, pale but generally normal individual with severe secondary anemia. Tarry stools were noted. The gastric secretion had a normal acidity but blood was present. The gastro intestinal series revealed a large portion of the stomach above the diaphragm with a definite constriction which divided the stomach into 2 portions. Her brother also had a diaphragmatic hernia. Exploration was advised and this was done by Dr Dan Jones in Boston. Her herniation was found present without constriction or

thickening of the stomach. Nothing else abnormal was found (Fig 14).

Occasionally, in spite of the severity of the symptoms, operation will be refused. In such an event treatment must of necessity be symptomatic and is not likely to be effective.

CASE 17 E B, No 58626, a female aged 69 years, was admitted to Rochester Municipal Hospital on March 21, 1932 because of abdominal pain and vomiting. The patient had been in good health till December, 1931. Then lower abdominal pain occurred with severe cramps, diarrhea, 10 to 15 stools daily, vomiting for 1 month, burning epigastric pain and belching for 2 weeks. Examination showed the patient to be well developed and nourished with adentia, thoracic kyphosis, emphysematous chest, arteriosclerosis, tenderness in both upper quadrants especially the right, and a palpable mass in the right upper quadrant. Vomitus contained blood. The gastro intestinal series revealed a large herniation of the stomach, 6 by 8 centimeters through the diaphragm. Surgery was advised but was refused. Vomiting continued and there was no improvement on discharge from the hospital.

The majority of patients with esophageal hiatus hernias have puzzling histories. There

Fig 23

Fig 24

Figs 23, 24 and 25 Case 54 These 3 roentgenograms demonstrate a thoracic stomach In Figures 23 and 24, 2 pouches are seen In Figure 23 the lower thorax is occupied by an air and fluid containing cystic area with an extension of a similar area to the left and below the left diaphragm The right diaphragm is above the stomach The esophageal opening is to the right of the median line and high up The whole stomach is between the right diaphragm and above the liver in Figure 25 This must be a freely mobile stomach which passes back and forth through a large defect posteriorly between the right and left leaves of the diaphragm The right diaphragm represents a true eventration There is a congenital shortening of the esophagus

CASE 23 W O, No 101098, a male, aged 62 years, was admitted to Rochester Municipal Hospital on April 7, 1935, suffering from vomiting, dizziness and weakness He vomited coffee ground material immediately after waking on the morning of admission This was followed by nausea and extreme weakness but no pain He had lost 35 pounds in 6 months He experienced occasional heart burn which was relieved by soda He was a heavy drinker, obese, pale, and slightly anemic with tarry stools The gastro-intestinal series showed a small diaphragmatic hernia A Sippy diet and rest were prescribed Stools were guaiac positive for 18 days, and he was discharged in good condition

CASE 24 A H, No 120834, a woman, aged 63 years, was admitted to Strong Memorial Hospital on October 23, 1936 Her complaints were heart trouble, stomach trouble and weakness, dropped beats, low blood pressure, poor appetite, frequent nausea and belching for 2 years The gastro-intes-

Fig 25

tinal series 2 years before were pronounced all right at another hospital She had been in bed most of the time since, had eaten little and had vomiting spells 2 weeks previously The general examination was

Fig. 20 Case 51. Herniations as large as this may not give any evidence of their presence when the patient is standing. Recumbency is necessary to show them.

some nausea but no vomiting. The patient was depressed but well developed and nourished. Her teeth were in poor condition and there was a moderate hypertension. Otherwise her condition was normal. The gastro intestinal series showed a small herniation through the esophageal hiatus, a small stomach but no ulcers. No symptoms were present while the patient was under medical treatment.

CASE 20. D. C. No. 122879, a male aged 47 years, was admitted to Strong Memorial Hospital on January 3, 1937. He complained of nervous exhaustion, headaches, weakness, and a constant desire to rest for a period of 7 years. Two months previous to admission he experienced discomfort after eating which was not relieved by milk but was always relieved by soda. He also complained of constipa-

Fig. 22 Case 53. Entire cardiac portion of stomach above diaphragm. Narrow constriction at orifice.

Fig. 21 Case 52. A large portion of the stomach herniates into the thorax in some cases.

tion and had lost 5 to 10 pounds in weight. The patient was poorly developed and nourished with slight exophthalmos and hypotension. Examination was generally negative. The gastro intestinal series showed a small herniation through the diaphragm at the cardia. The patient complained of pain on inspiration as the herniation occurred. He was discharged for medical treatment.

CASE 21. R. S. No. 84491, a male aged 36 years, was admitted to Strong Memorial Hospital on December 2, 1937. For 5 years the patient had suffered distress before meals which was relieved by soda or food. His case was diagnosed as duodenal ulcer here in 1934. When he followed medical instruction he was free from symptoms. In the last few months he complained of heart burn and vomiting. On the night preceding admission he vomited blood for the first time and his stool was black. Examination showed a normal individual except for a pyloric sinus and the presence of blood in stools. There was no anemia. The gastro intestinal series revealed a small esophageal hiatus hernia which improved rapidly under medication.

CASE 22. No. 127312, a female aged 54 years, was admitted to Strong Memorial Hospital on May 2, 1936. An appendectomy had been performed 3 years previously. The gall bladder was under suspicion at that time as a source of mild epigastric distress. The patient suffered for 1 year with gas immediately after eating which was relieved by belching. There was an increasing discomfort with a sense of crowding below the sternum and occasional precordial pain. Four nights before admission a severe bout of precordial pain radiated down the left arm, lasting 1 hour and requiring morphine. An oral cholecystogram was normal 3 years previously but her physician believed the gall bladder to be the base of her trouble. She was well developed. The gastro intestinal series revealed a small herniation through the esophageal hiatus, pyloric spasm and cardiospasm. There was no duodenal ulcer.

Fig 27 Case 36 Practically the whole stomach is above the diaphragm in this case (Three-fourths lateral view)

Fig 28 Case 36 The diaphragm level shows well below the thoracic stomach in this view.

of the kidneys also. In the course of his examination a small diaphragmatic hernia was noted at the esophageal hiatus. He died at home the next month.

CASE 31. R B, No. 25287, a male, aged 61 years, was admitted on May 25, 1930, to Rochester Municipal Hospital, with an impermeable stricture of the urethra. Mineral oil could be passed by the sphincter with little difficulty. Dilatation of stricture following mineral oil led to oil embolism of the lungs and kidneys. The patient died. On postmortem examination a diaphragmatic hernia was found on the left side.

CASE 32. F M O, No 99222, a man, aged 72 years, was admitted to Strong Memorial Hospital on February 13, 1935, with a prostatic obstruction. Two weeks previously there were anorexia, fullness in the epigastrium, gradual onset of nausea following ingestion of food, and constipation. Examination showed a heart slightly enlarged to the left and moderate sclerosis. General examination was normal. The gastro-intestinal series showed a small diaphragmatic hernia. A perineal prostatectomy was performed. He was discharged in good condition and has had no further stomach complaint.

It is not uncommon to note that the whole fundus has herniated through the esophageal hiatus. Cases 33 to 36 are typical examples.

CASE 33. M S, No 72433, a man, aged 56 years, was admitted to Rochester Municipal Hospital on May 6, 1937. For 3 to 4 months he had a chronic cough with yellowish sputum, which became bloody

in the last 4 days. There were vague anterior chest pains, some night sweats and questionable loss in weight, mild nausea and occasional vomiting. Examination showed the patient to be obese with chronic bronchitis, bronchiectasis, and chronic sinusitis. The gastro-intestinal series revealed a diaphragmatic hernia which consisted of the whole fundus of the stomach. He was discharged for medical treatment.

CASE 34. M N, No 60770, a woman, aged 50 years, was admitted 8 times to Rochester Municipal Hospital from May 9, 1932 to October 26, 1937, for gynecological complaints, hypertension, and diabetes. On her sixth admission, February 1937, she complained of diarrhea associated with epigastric pain. This came immediately after eating and lasted 2 to 3 hours, leaving a soreness in the epigastrium. Food aggravated the pain. The gastro-intestinal series showed a large sac of stomach herniated through the diaphragm at the esophageal hiatus and associated pylorospasm. On her last 2 hospital admissions, she complained of no symptoms referable to the epigastrium.

CASE 35. A P, No. 63663, a woman, aged 63 years, was admitted to Strong Memorial Hospital on June 5, 1936. Six weeks previously she noticed mucus and blood in her stools, also a dull aching in the left, lower quadrant. There had been gas on the stomach and belching but no other gastric symptoms. Examination showed a well developed and nourished individual with arteriosclerosis and mild arteriosclerotic heart disease. Blood was present in the stool. Barium enema was negative, stomach

Fig. 26 Case 53. Spiral twist of stomach which is all above the diaphragm except pyloric end. Multiple pancreatic calculi demonstrated below the stomach, confirmed at necropsy.

negative. She had lost 11 pounds in 2 months. The gastro intestinal series showed a small hiatus hernia with a duodenal ulcer suspected. Under medication the patient improved.

Case 25 simulates a cardiac complaint

CASE 25 J. D., No. 19924, a man aged 69 years was admitted to Rochester Municipal Hospital on September 8, 1937. On 2 previous admissions coronary occlusion and heart disease were proved by the electrocardiogram. Sharp retrosternal pain radiated to the fingers on the left side after exertion. Heart medication was given and there was a gradual recovery. There are now recurrent pains plus distention, nausea after eating, mild anorexia with a loss of 7 pounds in weight. The gastro intestinal series showed a herniation through the middle of the dome of the diaphragm when patient was in Trendelenburg position. The patient complained of pain on deep inspiration and said that this pain was what he ordinarily experienced.

Case 26 illustrates how symptoms may be latent for years in these cases, and then be come annoying.

CASE 26 A. P. No. 126460, a man aged 87 years was admitted to Rochester Municipal Hospital on April 16, 1937. He had been well till 6 months previously. Then a non productive cough, shortness of breath, sensation that there was something that caused difficulty in swallowing, hoarseness and loss of weight occurred. Examination showed signs of

age and a hypertrophied prostate. Barium showed an esophageal hiatus hernia. On smooth diet and belladonna the patient improved and was discharged for medical care.

Cases 27 to 32 had other associated diseases and small thumb sized para esophageal hernia tions.

CASE 27 G. T. No. 61193, a woman aged 41 years had been admitted 15 times to Rochester Municipal Hospital from May 14, 1932 to February 9, 1937. Previous entries were for tertiary syphilis, suspected cholecystitis, right hydronephrosis, double left ureter, pyelitis, cystitis, gynecological complaints, anxiety state, etc. Careful studies failed to reveal a definite organic basis for her numerous complaints. In 1 of her later admissions she complained of nausea, vomiting, and pain in the epigastrium after meals. The gastro intestinal series showed a small herniation through the esophageal hiatus on deep inspiration. There was also cardiospasm and slight pylorospasm but no ulcer. She was maladjusted, threatened suicide and the social problem was very complicated. She was symptomatically relieved by medication. She was told about her stomach and has had relapses of her symptoms from time to time.

CASE 28 M. O., No. 39164, a woman aged 77 years was admitted to Strong Memorial Hospital on November 16, 1936. Eighteen months previously there had been an onset of pain in the right shoulder, generalized later over the back which lasted 2 weeks. This was followed by a persistent non radiating pain over the entire lower abdomen without nausea or vomiting. Her mother died of carcinoma of the breast and her son had carcinoma of the colon. An appendectomy was performed 10 years previously and a gall bladder operation 27 years before. The patient was obese, with degenerative arthritis and hypertension. The remainder of the examination was normal. The gastro intestinal series showed a small herniation through the esophageal hiatus, diverticula of the duodenum and gastric and duodenal ulcers. She was asymptomatic during medical treatment.

CASE 29 E. S. No. 121036, a male aged 61 years was admitted to Strong Memorial Hospital on November 4, 1936, suffering with loss of strength and a sore tongue. For 6 weeks there had been puffiness of eyelids, palpitation of heart and pain radiating down the left arm. This was relieved by rest. He had typhoid at 16 years of age and had a yellowish appearance. When given liver and iron he improved. Diagnosis revealed pernicious anemia. The gastro intestinal series showed a small diaphragmatic hernia at the esophageal hiatus and pylorospasm. He improved under medical care.

CASE 30 A. C. No. 111371, a male aged 73 years was admitted to Rochester Municipal Hospital on January 24, 1936, with generalized tuberculosis, pulmonary, intestinal and peritoneal and probably

rate diagnosis becomes increasingly difficult. In our esophageal hiatus hernias we have noted the presence of the degenerative disease of age (arteriosclerosis, heart, kidney, diabetic, and prostatic conditions), pneumonia, syphilis, cholecystitis, gastric ulcer, cancer of the rectum and colon, and acute appendicitis.

The 4 following cases illustrate these difficulties. The patients all had very serious pathological conditions in addition to the herniation of the fundus. In all cases from Cases 33 to 43 there was as large a portion of the fundus herniated as is shown in Figure 15.

CASE 40. L G, No. 48186, a woman, aged 60 years, was admitted to Strong Memorial Hospital on January 6, 1934. She was a garrulous Irish woman who would not give a consistent story. One gathered that she had considerable pain in the lower thoracic and upper abdominal regions. It radiated under the sternum, was aggravated by eating, and relieved by hot water. There was also spasm and bleeding from the rectum. The patient also had a cough, with mucopurulent sputum. Examination showed loss of weight, hypertension, an area of dullness at the right base posteriorly with diminished breath and voice sounds, prolapse of the rectum, moderate secondary anemia and no fever. Roentgenograms showed a dense shadow on the right lung extending from the seventh posterior rib to base. The gastro-intestinal series revealed a herniation at the cardiac end of the stomach through the diaphragm. The shadow in the right chest varied in size. The patient remained in the hospital for 3 months and improved under medical treatment. Impression was that there was carcinoma of the lung and a hernia of the diaphragm. She died on May 11, 1937 at her home. The cause of death is unknown.

CASE 41. C P, No. 128726, a male, aged 46 years, was admitted to Strong Memorial Hospital on June 6, 1937. There had been a gradual onset of gnawing pain in the mid epigastrium, associated with nausea and vomiting for 4 days, vomitus was chocolate colored and blood streaked. Since then vomiting, distention and hiccoughs have continued. Temperature was 100.5, pulse 80, white blood cells, 7,300. The patient was undernourished, pale, dehydrated, and suffered loss in weight. There was a moderate distention and tenderness in the left para-umbilical region. The stool was guaiac plus, gastric analysis was also guaiac plus. The gastro-intestinal series revealed a 6 centimeters diaphragmatic hernia of the stomach with spasm of the pylorus and palisading of the small bowel. He was observed six days but there was no improvement. Exploration showed a gangrenous appendix and generalized peritonitis. Death followed 5 days after operation.

CASE 42. R T, No. 117284, a male, aged 78 years, was admitted to Rochester Municipal Hospital on July 21, 1936. The patient gave a history of occa-

sional mild substernal pain with cough, hemoptysis, night sweats, weakness, loss of weight, emaciation, and cyanosis. There were a few râles at both bases, otherwise the lungs were normal. Roentgenogram revealed a probable infiltrating carcinoma of the right lower lobe. The gastro-intestinal series showed a herniation of the fundus of the stomach through the esophageal hiatus with fixation within the thorax. The patient died in August, 1936. Autopsy showed organizing pneumonia, pyelonephritis, and general arteriosclerosis.

CASE 43. A S., No. 82548, a female, aged 57 years, was admitted to Strong Memorial Hospital on November 22, 1933. She entered because of acute urinary retention. Cystitis with a narrowing of the urethra was found. She also had a change in bowel habits, 6 to 8 months of increasing constipation and blood in the stools. Barium enema was negative, the proctoscope revealed hemorrhoids. The gastro-intestinal series showed delay and herniation of the stomach wall through the esophageal hiatus. The patient was readmitted on August 19, 1935, with increasing constipation, vomiting, pallor, and distention. Barium enema was again negative. After exploration showed carcinoma of the hepatic flexure, a cecostomy was performed. Death occurred on the following day.

The presence of syphilis in some of these patients may also render an accurate evaluation of symptoms difficult. Five such examples are here given.

CASE 44. M M, No. 89744, a woman, aged 24 years, was admitted to Rochester Municipal Hospital on May 20, 1934, because of vomiting, loss of appetite, loss of strength, and a loss of 20 pounds in weight during the previous month. This followed an attack of influenza. Examination was negative except for slight anemia, Wassermann was 4 plus, cholecystogram was normal. The gastro-intestinal series revealed a small hernia through the esophageal hiatus. There was a gradual improvement under medical treatment.

CASE 45. H M, No. 89022, a male, aged 44 years, was admitted to Strong Memorial Hospital on May 6, 1934, because of vomiting. For 8 to 9 years the patient suffered with epigastric oppression which was relieved by soda and eructations. He had been well till 5 days previously, then nausea set in, which was relieved by soda, but he had been vomiting repeatedly since. He had had chancre 15 years before and occasional transitory pains in the heels, Wassermann was 2 plus. At examination findings were normal. The gastro-intestinal series revealed a hernia of the stomach through the diaphragm but no ulcer. Under rest, diet, and drugs he became symptom free and was discharged. The patient returned in 5 days with a recurrence which was again controlled when he was put on an antiluetic treatment.

CASE 46. F K, No. 25149, a male, aged 57 years, was admitted to Strong Memorial Hospital on June

Fig. 29. Case 57. It is advantageous to demonstrate the end of the esophagus in these cases. It shows well here and it is apparently congenitally shortened. The diaphragm levels are well seen below in this lateral view.

acidity was normal. The gastro intestinal series revealed no evidence of ulcer or cancer. There was a herniation of the fundus through the esophageal hiatus. She improved under medical treatment and was reassured regarding cancer.

CASE 36. V. K. No 30360 a woman aged 52 years was admitted to Strong Memorial Hospital on December 4, 1929. Four weeks previously she awakened feeling weak, nervous and dizzy and these symptoms persisted. Her physician sent her to the hospital because of blood in the stools. Examination revealed varicose veins, hallux valgus, kyphosis and secondary anemia. The gastro intestinal series showed a herniation of the cardiac end of the stomach through the esophageal hiatus. There was no evidence of gastric ulcer or cancer. Barium enema was negative. Proctoscopic inspection revealed hemorrhoids only and the patient was discharged for medical care.

Cases 37 and 38 had definite evidence of diseased gall bladders in addition to the gastric complaints.

CASE 37. C. M. No 70195 a man aged 53 years was admitted to Rochester Municipal Hospital on January 12, 1933. He gave a history of stomach trouble dating from typhoid 23 years previously. Ever since he had a dull, heavy feeling in the mid epigastrium, heart burn, belching, occasional nausea

and vomiting which gave relief. Discomfort was not relieved by meals but was aggravated instead. He dreaded the thought of eating but had gained in weight in the last 1½ years. When he bent forward he had a feeling that everything would come out of his mouth. Examination showed a man well developed and nourished with slight hypertension and hemorrhoids. The impression was gastric lesion and cholecystitis. The gastro intestinal series revealed a herniation of the stomach through the esophageal hiatus. The cholecystogram showed chronic cholecystitis. He received symptomatic treatment and improved. He now has occasional attacks of burning which are relieved by soda and diet.

CASE 38. H. S. No 126260 a male aged 77 years was admitted to Strong Memorial Hospital on April 3, 1937. He had been well till 3 years previously when he began to lose weight. Six days before admission he felt a sudden, progressively severe epigastric pain coming on while at rest which radiated over the entire upper abdomen, more to the right than to the left. Later vomiting occurred with tarry black material and continued nausea. He was afraid to eat and lost weight rapidly. He had a similar attack 20 years before and suffered with typhoid at 45 years of age. There was fullness and tenderness in the right upper quadrant and epigastrium and blood in the stools. The gall bladder test was positive for stones. He had evidence of myocardial damage. The gastro intestinal series revealed a large diaphragmatic hernia and a diverticulosis of the large bowel. Rapid improvement was brought about under medical treatment.

In case 39, the large fundus herniation was discovered when barium was given by mouth to check on the possibility of a partial obstruction of the small bowel. The patient had had a resection for carcinoma of the rectum 1 year previously.

CASE 39. J. M. No 106067 a woman aged 67 years was admitted to Strong Memorial Hospital on August 11, 1936. In August 1935 she had been in the hospital for resection of carcinoma of the rectum. Since discharge she had had cramp-like pains 2 to 3 times a week, located around the umbilicus on the right, followed by diarrhea. She had gained 13 pounds since she was discharged from the hospital. General examination was not remarkable. The colostomy opening was redundant. The gastro intestinal series showed a diaphragmatic hernia of the stomach through the esophageal hiatus. There was fixation and slight obstruction due to diaphragm spasm. There was no intestinal obstruction in the small bowel. The patient improved under careful regulation of diet and catharsis.

When patients have reached later life and other diseases are actually present, the accu-

showed chronic bronchitis, emphysema and arteriosclerotic heart disease. In the course of her examination, a diaphragmatic hernia through the esophageal hiatus was noted. It was chiefly seen on deep inspiration, on coughing or straining. She was asymptomatic in the hospital (Fig. 18).

CASE 50 B D, No 23844, a woman, aged 58 years, was admitted to Strong Memorial Hospital on March 6, 1935. Two years previously she had complained of increasing fatigue, gain in weight, shortness of breath on stair climbing, also attacks at night in which she feared death. These attacks consisted of severe lancinating pains and soreness of the right costal margin. After large meals there was indigestion with pressure upward on the left side which could be relieved by belching. Several months before she developed a dull, non-radiating pain in the left upper quadrant. It was more marked on exertion and on lying down. If it came on in recumbency, she got some relief by getting up. The condition gradually grew worse. Examination showed moderate anemia and obesity. The gastro-intestinal series revealed a large para-esophageal hernia and possible gastric ulcer. She had been comfortable under medical regimen (Fig. 19).

CASE 51 D B, No 21060, a woman, aged 77 years at last admission, was first admitted to Strong Memorial Hospital on January 11, 1929. She has had 4 admissions since, mainly for cardiac and diabetic complaints. She was thought to have chronic cholecystitis because of resistance and tenderness in the right upper quadrant. Cholecystogram was within normal limits. The gastro-intestinal series showed a herniation of the upper portion of the stomach through the esophageal hiatus. It produced no motility disturbance (Fig. 20).

CASE 52. C K, No 72927, a woman, aged 67 years, was admitted to Rochester Municipal Hospital on March 20, 1933, for frequency, dysuria, and pain in the right side which lasted 4 months. Stereopyelogram showed ptosis of the right kidney with hydronephrosis, and double ureter on the left side. For 25 years she had had attacks of severe epigastric pain and vomiting. The pain grew worse at night and was somewhat relieved by lying on the left side. A cholecystectomy had been performed 27 years previously. Examination revealed an emphysematous chest, hypertension, a scar in right upper quadrant, and a palpable right kidney. The gastro-intestinal series showed herniation of a large portion of the stomach through the esophageal hiatus. Symptomatic treatment only was given (Fig. 21).

CASE 53 M B, No 48659, a woman, aged 66 years, was admitted to Strong Memorial Hospital on June 24, 1931, because of weakness, anemia, excessive gas, and constipation for 1 year. There had been occasional icterus and clay colored stools, also sharp pain under the right costal margin and into the low back. The patient had lost 15 pounds in weight and had had colitis and dysentery for 5 years. Examination revealed the patient to be overnourished with moderate anemia, slight enlargement of

the heart, mild hypertension, and guaiac positive stools. The gastro-intestinal series showed the entire cardia through the diaphragm. Medical treatment gave relief (Fig. 22).

The partial thoracic stomach which extends through the esophageal hiatus may also give puzzling signs. In consequence, diagnosis of pulmonary cavity, pleural fluid, thickened pleura, bronchiectasis, pneumonia, mediastinal tumor and pulmonary carcinoma have been made in these cases.

The roentgenogram again furnishes the complete evidence and often demonstrates a bizarre arrangement of the organs in the thoracic cavity. Case 54 is a typical example of a thoracic stomach. The flat plate shows a large cystic area in the lower right thorax. It has a fluid level. The lateral view shows it to be 2 gastric pouches; and the barium demonstrates that the whole stomach occupies the right lower thorax. The greater curvature of the stomach is to the right and the cardia, pylorus, and lesser curvature toward the medial side.

CASE 54 B R, No 98019, a woman, aged 46 years, was admitted to Rochester Municipal Hospital on October 16, 1936. She had had gaseous indigestion for 4 years, and $2\frac{1}{2}$ years previously nausea and vomiting occurred 1 hour after meals. This condition was relieved somewhat by soda. There was an increasing burning pain in the epigastrium. In the past 2 years she had lost 30 pounds in weight and felt full after she had taken a small amount of food. She had received treatment without avail. For 24 years she had suffered with rheumatism and had well developed, crippled joints, an enlarged thyroid, and moderate hypertension. There was a dull percussion note in the right lower lobe, posteriorly; breath sounds were diminished, vocal fremitus and tactile fremitus were present in the same area, and there was a splashing sound heard after shaking the chest. Laboratory findings were negative. A diagnosis suggested stomach ulcer or cancer and right pleural effusion. The gastro-intestinal series showed a right-sided intrathoracic stomach with a large out-pocketing along the lesser curvature, probably a diverticulum. Medical treatment was advised (Figs. 23, 24, 25).

Case 55 illustrates the rotation of a major portion of the stomach in the thoracic cavity with only a small portion of the pyloric end subdiaphragmatic.

CASE 55 T N, No 110808, a woman, aged 61 years, was admitted to Rochester Municipal Hos-

3 1929 He gave a history of mid epigastric pain for 3 months a dull steady, nearly constant pain sharply localized high in the mid epigastrium Occasionally it was parasternal given to acute exacerbations which was precipitated by varying postural changes, and relieved in the same manner and by rest Examination showed enlarged glands slightly enlarged heart, moderate sclerous pupils sluggish to light, arthritis especially of the dorsal spine, and Wassermann 4 plus The gastro intestinal series revealed a hernia through the esophageal hiatus Pain was controlled largely by antiluetic treatment Occasional attacks like indigestion lasted 1 hour

CASE 47 M B, No 127835 a woman, aged 40 years was admitted to Strong Memorial Hospital on December 28, 1936 At a previous admission in February, 1936 examination revealed a mild, toxic nodular goiter Since then there had been symptoms of indigestion gas occasional right upper quadrant pain palpitation, and transient dizziness Improvement was brought about with belladonna The patient was nervous, emotional, with a large thyroid, but otherwise was normal physically Wassermann tests on 3 occasions were one plus, two plus and negative respectively The gastro intestinal series showed a small diaphragmatic hernia at the cardia The patient complained of pain on deep inspiration as the stomach herniated There were associated cardiospasm and pylorospasm She was put on medical treatment with still persisting mild symptoms

CASE 48 J B, No 1736 a male aged 52 years was admitted to Strong Memorial Hospital on July 7 1926 For 3 years the patient had a run down feeling and in June 1925, had to give up work because he was weak and anemic He was treated for pernicious anemia until January 1926, but there was a gradual decline through winter with vague stomach and chest pains The patient had had chancres 32 years previously Patient was sallow, and had peculiar rumbling sounds over the precordium There was a percussion note at times tympanic over the heart region splashes and clicks synchronous with heart beat, tenderness in the epigastrium, and absence of knee jerks and secondary anemia Wassermann 4 plus The gastro intestinal series showed a diaphragmatic herniation of stomach and diverticulum of stomach below the diaphragm The patient was put on antiluetic treatment and improved

In Case 48 the roentgen ray demonstrated a very unusual picture In addition to the large intrathoracic sacculization, which appeared like a cystic area in the lower left chest there was also a diverticulum extending laterally from the greater curvature below the diaphragm Figs 16 and 17

The diagnosis can be suspected from the symptoms and signs It is clinched by the

roentgen examination Barium may be necessary in a gastro intestinal series or in a clystma in order to show the lesion The esophageal hiatus hernias can be noted occasionally in the upright position, but usually the lesion is much more pronounced when the patient is reclining It may even require deep inspirations to demonstrate the small portion of the cardia above the diaphragm Sometimes the air bubble will be sufficient to outline the herniation (Fig 18) As a rule a swallow of barium demonstrates the lesion accurately This must be differentiated from cardiospasm, and diverticulum of the esophagus It is simplified when the rugæ of the cardia can be traced directly into the sacculization across the intervening diaphragm which causes a constriction about the area (Fig 12) It is often surprising how large a portion of the stomach can be demonstrated above the diaphragm when the patient is prone, only to have it completely subside below the diaphragm level on standing (Fig 20)

Esophagospasm (Fig 11) and cardiospasm are often associated, and frequently pylorospasm as well This makes the diagnosis of intramural gastric lesions difficult The barium by mouth will many times give definite fluid levels, indicating the partial stasis which is present in some of these stomachs (Figs 13 and 14) Transition to the true thoracic stomach can be determined only by demonstration of the length of the esophagus If it is present and curled back upon itself so that the stomach could be put back below the diaphragm if necessary, the case is a true hiatus hernia (Fig 11) In the true thoracic stomach the esophagus is congenitally shortened, making subdiaphragmatic restoration of the stomach impossible Consequently, it is important to visualize completely the esophagus in all these patients Some hiatus hernias contain a large portion of the stomach (Figs 21 and 22) Cases 49 to 53 show the radiographic appearances described above

CASE 49 G R, No 120760 a woman aged 67 years was admitted to Strong Memorial Hospital on October 30, 1936 She had had jaundice with fever at 19 years of age Appendectomy had been performed 12 years previously Her present admission was concerned with attacks of bronchitis There were no symptoms referable to the stomach Examination

catheter through the hernia opening to equalize the pressure was suggested by Mayo. It is a useful procedure in a difficult case.

Minor types of esophageal hiatus hernia may be relieved by simple phrenic nerve block though this is not always successful. This method is also applicable to very old or debilitated patients who will not stand a procedure of greater proportions. Care should be taken to determine just what position the stomach and esophageal junction will assume. In case this is not done the angulation between the esophagus and the stomach may be increased and the symptoms may become worse. The excellent studies of Lichtenstein on this question should be known to surgeons contemplating this procedure. At times the right phrenic probably should be the nerve temporarily paralyzed (19).

In some cases of thoracic stomach in which there is a pinch-cock action of the edges of the diaphragm on the herniated organ, a phrenic block will give relief (Case 57). In other cases, no benefit follows this procedure (Case 58).

When the spleen is adherent inside the sac of an esophageal hiatus hernia, it may tear easily if handled while the respiratory excursions are greatly forced. This forms a complication which may be very serious. The spleen should either be sutured if possible (Case 14) or removed if necessary under such circumstances.

BIBLIOGRAPHY

pital on January 10 1936 She had lost 50 pounds in 6 months Five months previous she had had a watery diarrhea associated with nausea, bloating and loss of appetite There was extreme weakness palpitation dyspnea and spots before the eyes Three weeks before admission she had a second bout of diarrhea with blood in stool and had fainted several times recently At 15 years of age he had typhoid and had an appendectomy performed 30 years previously Examination revealed pallor pyorrhea, moderate deterioration severe secondary anemia, complete achlorhydria, chronic cholecystitis (intra venous cholecystogram) and pancreatic calculi The gastro intestinal series showed short esophagus, cardia of the stomach above the diaphragm, body of the stomach curled upward for 15 to 20 centimeters behind the heart and to the right of cardia portion then downward and to the left through the diaphragm Only one fifth to one sixth of the entire stomach was below the diaphragm She gradually became worse Ascites developed with thrombosis of the left iliac Death occurred on March 3, 1936 Anatomical diagnosis revealed multiple pancreatic calculi with complete atrophy tuberculosis of the peritoneum, diaphragm, left pleura, spleen, and right adenal, multiple pulmonary emboli and herniation of the stomach through the diaphragm (Fig 26)

Cases 56 and 57 show further variations in these gyrating, twisting, gastric herniations above the diaphragm

CASE 56 A W, No 116904 a woman, aged 72 years, was admitted to Strong Memorial Hospital on August 2 1936 The patient gave a history of pain in the stomach and right upper quadrant with a sudden onset 8 years previously of spells of nausea and persistent vomiting repeated frequently since There was a swelling in the right epigastrium at onset and at varying intervals There was also much pain, which was relieved by vomiting Vomitus contained blood and stools were tarry She was unable to retain solid food Her last severe attack occurred 6 months before The patient lost 28 pounds in 2 years Examination revealed the patient to be senile with general arteriosclerosis, hypertension, arteriosclerotic heart disease, and tenderness in the epigastrium The gastro intestinal series showed herniation of the stomach through the esophageal hiatus 6 centimeters of fundus above the diaphragm irreducible, and marked pylorospasm There was a suggestion of ulceration at the level of the diaphragm and also in the duodenum Owing to age and general poor condition phrenic nerve block was done under local anesthesia She did not have any improvement following this therapy There were many unrelated aches and pains in all parts of the body (Figs 27, 28)

CASE 57 M No 127376 a female aged 55 years was admitted to Strong Memorial Hospital on May 10 1937 Three years before there was an on-

set of severe epigastric pain during meal or immediately after which was relieved by drinking water or by vomiting This occurred once or twice a week with belching and flatulence Roentgenogram showed a diaphragmatic hernia and diverticula in the large bowel Medical treatment was administered but symptoms increased Occasional pain radiated to the left shoulder Examination was essentially normal The gastro-intestinal series showed about three fourths of the stomach intra thoracic and posterior with pinch cock action at the lower end of the stomach A left phrenic nerve crush was employed and the patient obtained some relief (Fig 29)

The esophageal hiatus type may be very difficult surgery It may require approach through the chest or from the abdominal side Sometimes, even when approached from both angles, it is practically impossible to visualize a small sac In such a case, packing may be successful in causing adhesions with relief of symptoms Case 58 is an example

CASE 58 S H, No 6350 a woman aged 43 years was admitted to Strong Memorial Hospital on July 6, 1932 For 6 years she suffered attacks of vomiting accompanied by knife like pain in the left upper quadrant radiating to the infrascapular region Attacks occurred usually at night lasting several hours These were accompanied by a bloated feeling in the epigastrium and severe eructations Cholecystectomy and appendectomy were performed 4 years previously with relief for 3 months For the last 4 years she had been vomiting nightly with severe colic like pains She obtained no relief from food or soda and there was blood in the vomitus occasionally during the last 6 months A diagnosis of duodenal ulcer was made 1 year before Examination revealed the patient to be very obese There was gas gurgling and she was belching almost continuously The gastro intestinal series was negative except for herniation of the stomach through the esophageal hiatus Operation was performed by abdominal route by tran thoracic and by both It was impossible to visualize the opening though it could be palpated Drains were inserted into it from the abdominal side Nausea and vomiting disappeared and the patient could eat anything She has had relief from her symptoms since discharge from the hospital

The operation described by Harnington is very useful (14, 15) Temporary paralysis of the diaphragm greatly facilitates the task of repair The edges should be approximated with care It is not necessary to suture into the esophagus if the repair is properly carried out Fruesdale has given some excellent advice in this regard (23) The passage of a

sisted of 20 blows to 1 thigh with a heavy iron bar, the femur being broken. In their paper (15) in 1935, they state, "Our first conclusion is that a toxemia, due to the elaboration of histamine or any other depressor substance manufactured in the traumatized area, plays no part in the syndrome of traumatic shock. We regard the 2 remaining factors, local fluid loss and the discharge of nociceptive nervous stimuli, as the effective etiological agents. The evidence does not allow us to dogmatize as to the relative importance of these factors, although we are inclined to believe that the nervous factor dominates the picture." In a later communication (18), they state, "The initial depressor effect of trauma is due to fluid loss; the significant secondary decline to shock is caused by the continued and continuous discharge of nervous impulses from the traumatized area. The nervous factor alone can cause death. The fluid loss in these experiments, provided the nervous factor is controlled, is not fatal." Their methods differ in the main from those of others in that chloralose was used as the anesthetic and the blows were inflicted with an iron bar rather than a hammer or mallet.

Of the many types of experiments performed by O'Shaughnessy and Slome, the two following types seem to be the most significant. It was found that the induction of spinal anesthesia has a most favorable influence in delaying and even preventing the onset of shock in cats anesthetized by chloralose. Second, they found that shock followed trauma to an extremity of an animal in which the limb received its circulation from a second cat. Bell, Clark, and Cuthbertson were unable to repeat these latter findings on cats anesthetized by nembutal. They state, "In none of the experiments was there any evidence that traumatization of the recipient's transfused limb caused anything but a temporary disturbance of the recipient's blood pressure. This is directly opposed to the finding of O'Shaughnessy and Slome. In their 2 recorded cross-circulation experiments, the recipients went into shock and died, and in 1 they found that trauma caused death of the donor some 2 hours after the injury and actually before the recipient went into shock."

A number of experiments have been performed previously which may have a bearing on their observations on the use of spinal anesthesia. Parsons and Phemister found that the traumatization of denervated limbs of dogs resulted in low blood pressures similar to those produced in animals whose limbs were not denervated. As stated, Freedlander and Lenhart obtained similar findings in cats. Blalock (4) found that trauma produced its characteristic effects in dogs after spinal anesthesia had been induced. Holt and Macdonald (12) have found no evidence which supports the view that nociceptive nervous stimuli from the injured tissues dominate the picture in dogs anesthetized with sodium barbitone.

The present investigation consists of an attempt to assess the parts played by fluid loss and by nervous impulses in the onset of shock due to trauma. As stated, O'Shaughnessy and Slome used chloralose as the anesthetic and therein may rest the explanation for the discrepancy between their results and those of others. For this reason, the effects of the same procedures under chloralose and under nembutal anesthesia have been compared. It may not be amiss at this point to quote several authorities on the properties of chloralose. Cushny (7) states that chloralose is a sugar compound of chloral which acts much more like morphine than like chloral. It depresses the psychical functions while increasing the reflexes until convulsions resembling those of strychnine may be produced. Sollman states that chloralose is often contaminated with non-hypnotic but toxic parachloralose. It is stated in the *United States Dispensary* (20) that the action of chloralose is variable and that it may produce collapse, convulsions, or pronounced disturbances of respirations.

METHODS AND RESULTS

The experiments were all performed on cats or dogs and chloralose or nembutal was used as the anesthetic. The anesthetic was introduced intravenously. The initial dosage per kilogram of body weight of chloralose was 0.08 grams and of nembutal was 0.025 grams. In the course of the experiment additional doses were given as required. There was no

EXPERIMENTAL TRAUMATIC SHOCK FURTHER STUDIES WITH PARTICULAR REFERENCE TO THE RÔLE OF THE NERVOUS SYSTEM

ALFRED BLALOCK, M D F.A.C.S., and RALPH D CRESSMAN, M D Nashville, Tennessee

MUCH experimental work has been done on the shock that is associated with trauma to an extremity. This method (5) is of particular value in that the opposite extremity may be used as a control and the loss of blood into the injured part may be determined (2). Unfortunately in some instances, the results of such experiments have been interpreted by the investigator himself, or more often by the reader, as explaining all types of shock. This has led to confusion as there are several types of shock and all instances cannot be explained satisfactorily by one theory. The terms hematogenic, neurogenic, and vasogenic have been suggested (3) as names for the different types. Many instances of shock are probably combinations of 2 or all of these.

The 3 most popular theories at the present, as to the causation of shock, maintain that it is due to toxemia, to local fluid loss or to nervous stimuli. It is likely that all 3 of these agencies enter into the production and maintenance of some cases of shock. The most important point is to determine the agency or agencies responsible for the development of shock as there are probably countless factors which serve to maintain it after it is fully developed. If our remarks are limited to the shock that follows severe trauma to an extremity of an experimental animal, it would seem from many recent experiments that toxemia as an important initiating factor has been excluded. Dale stated recently, "With regard to the possible rôle of histamine, we know now what we did not know then, that

of all the major tissues of the body, the muscles contain least of that substance. What ever else it may have been, the shock following the Bayliss Cannon limb trauma was not histamine poisoning." However, this does not mean that the possibility of the absorption from injured tissues of substances which act slowly and over a long period has been excluded. There is good evidence that deaths which occur a number of days following burns are due in part at least to the action of toxic products.

It was found by Blalock (2) and by Parsons and Phemister that severe trauma to an extremity of a deeply anesthetized dog was associated with the loss of a sufficient part of the blood volume into and near the traumatized area to account for the decline in the blood pressure. These findings have been confirmed by Freedlander and Lenhart, by Holt and Macdonald and by others. Freedlander and Lenhart in their experiments used cats anesthetized by the intramuscular injection of sodium barbital in which the degree of injury was carefully controlled. They state, "With this large series as a control, experiments were conducted to exclude all the nervous connections of the extremity to be traumatized. In order to accomplish this, recovery experiments were done in stages, cutting the cord, the peripheral nerves, and the sympathetic chain. These completely denervated limbs responded to trauma like the controls. The shock following trauma can be explained on the basis of hemorrhage and local fluid loss."

Simonart concluded as a result of experiments on cats that an intact nerve supply is essential for the development of traumatic shock. Recently O'Shaughnessy and Slome have performed many experiments on cats anesthetized by chloralose. The trauma con

and non-traumatized extremities in the animals which received spinal anesthesia was 2.87 per cent of the body weight while that in those without the spinal was 3.59 per cent. A decrease in the concentration of the red blood cells occurred in most of the experiments.

As has been stated, the blood pressure in these experiments was determined by puncturing intermittently the exposed carotid artery with a needle which was connected to a mercury manometer. Cats survive longer as a rule when this method is used instead of placing a cannula in the carotid. This may be due to the loss of blood that occurs when it is necessary to wash out the cannula due to the clotting of blood.

Nembutal There were 16 experiments of this type on cats anesthetized by nembutal. Trauma in all instances consisted of 20 blows with an iron bar thus breaking the femur. The blood pressure was determined in the carotid artery by the needle puncture method. Eight animals served as controls and the other 8 were given spinal anesthesia before the trauma and every 30 minutes afterward for 7 or 8 hours. Six of the 8 animals which received no spinal anesthesia were alive at the end of 24 hours and were killed. The blood pressure was definitely depressed in 2 of these. One of the 8 died 4 hours and 35 minutes following the trauma and the remaining animal lived 22 hours and 30 minutes. The animal with the short survival period was extremely anemic, the control hematocrit reading being 17 and it declined to 13. The average difference in the weights of the traumatized and non-traumatized extremities in the 7 experiments in which it was determined equalled 3.55 per cent of the body weight. Six of the 8 animals that received a spinal anesthetic were alive at the end of 24 hours and were killed. The blood pressure was definitely depressed in 3 of these. The 2 remaining animals died 21 hours following the trauma. The average difference in the weights of the traumatized and non-traumatized extremities in the 6 experiments in which it was determined was 3.03 per cent of the body weight. The results in the 2 types of experiments, with and without a spinal anesthetic, were practically identical. There was very little altera-

tion in the hematocrit reading in 11 of the 16 experiments, a moderate rise in 1 and a moderate decline in 4.

GROUP II. DOGS. TRAUMA, CHLORALOSE, WITH AND WITHOUT SPINAL ANESTHETIC

As has been stated, O'Shaughnessy and Slome produced shock in cats by striking the thigh 20 blows with an iron bar thus breaking the femur. This method was used in our first 6 experiments on dogs anesthetized by chloralose. Two of the animals did not develop shock and were killed approximately 26 hours subsequently. The average survival of the 4 remaining animals was 9 hours and 45 minutes, the time ranging from 55 minutes to 20 hours. The difference in the weights of the 2 extremities ranged from 3.14 to 5.23 per cent of the body weight, the average being 4.19 per cent. Fourteen experiments were then carried out in which the traumatization consisted of 40 blows with an iron bar, the femur being broken. Two of these animals were not in shock 23 hours subsequently and were killed. The survival period in the 12 remaining experiments varied from 2 to 25.5 hours, the average being 9 hours and 37 minutes. The difference in weights of traumatized and non-traumatized extremities varied from 1.19 to 4.85 per cent of the body weight in the different experiments, the average being 3.23 per cent. All of the animals showed an increase in the concentration of the red blood cells. Addition of the 2 types (20 and 40 blows) shows that the average survival period in the 16 experiments in which trauma resulted in shock was 9 hours and 32 minutes and the average difference in weights of the extremities was 3.47 per cent.

The second type of experiment was similar to that just described except that spinal anesthesia was administered before the traumatization and every 30 minutes thereafter unless the animal lived longer than 7 or 8 hours. There were 5 experiments in which the injury consisted of 20 blows with an iron bar. Two of these did not get a marked decline in blood pressure and were killed at 6 and 10 hours, respectively, following the injury. The 3 remaining lived 5 hours and 40 minutes, 8 hours, and 17 hours and 20 min-

evidence of pain during the course of the experiments. The arterial blood pressure was determined in most instances by the use of a carotid cannula which was connected to a mercury manometer. In the remaining experiments, the exposed carotid artery was punctured with a needle which was connected to a manometer. The trauma consisted of striking the thigh with an iron bar, as used by O'Shaughnessy and Slome, thus breaking the femur. The increase in the weight of the traumatized extremity was determined by the amputation method (2) which was described previously by one of us. In the experiments in which spinal anesthesia was induced, the fluid was introduced intrathecally in the lower lumbar region. The dosage of the spinal anesthetic was the same as that used by O'Shaughnessy and Slome (15), namely, 1.66 milligrams novocain in 0.3 cubic centimeters of water per kilogram of body weight. The methods used in the cross circulation experiments were similar to those employed by O'Shaughnessy and Slome (15). The distal ends of the divided femoral artery and vein of 1 animal (recipient) were anastomosed by suture to the proximal ends of the carotid artery and external jugular vein of a second animal. The extremity of the recipient was then rendered *anemic* by the method of O'Shaughnessy and Slome, namely, ligation of the abdominal aorta, ilio-lumbar artery, middle sacral, external iliac, profunda femoris, the femoral artery and its branches in the groin and the veins corresponding to these arteries. Following this, the clips were removed from the vessels which had been connected by suture and the extremity was traumatized. According to O'Shaughnessy and Slome, the traumatized extremity receives blood only from the second animal and yet the reflexes are maintained intact.

Several different groups of experiments were performed.

GROUP I. CATS TRAUMA, WITH AND WITHOUT SPINAL ANESTHETIC

Chloralose These experiments were performed in pairs. Both cats received chloralose and 1 of the 2 received a spinal anesthetic before and at 30 minute intervals following

the traumatization for a period of 7 to 8 hours. The trauma consisted of 20 blows with an iron bar thus breaking the femur. Sixteen cats were used in this study, thus making 8 complete experiments in which animals with and without the spinal anesthetic were compared. The animal with the spinal anesthetic lived longer than the control animal in 6 of the 8 experiments, the reverse was true in 1 experiment and there was no difference in the remaining 1. There seemed to be little doubt that cats anesthetized with chloralose withstand trauma to a posterior extremity better if a spinal anesthetic is administered before and following the trauma. The results in the 16 experiments were as follows. Three of the cats with the spinal anesthetic were killed 25 or more hours following the traumatization. The blood pressure of only 1 of the 3 was markedly depressed. The average survival of the 3 remaining was 18 hours and 50 minutes and the average fluid loss in these equalled 3.12 per cent of the body weight. Of the cats without spinal anesthesia, 1 had a normal blood pressure 26 hours after the traumatization and was killed. The average survival of the 7 remaining was 13 hours and 15 minutes and the average difference in weights of the traumatized and non traumatized extremities equalled 3.26 per cent of the body weight. A moderate decrease in the concentration of the red blood cells was found in most of the experiments.

O'Shaughnessy and Slome found that the giving of a spinal anesthetic to cats already in shock as a result of trauma increased the survival period. These experiments were repeated on 5 pairs of cats. Shock was produced in the usual manner. After the blood pressure reached a shock level, 1 cat in each group was given a spinal anesthetic and this was repeated every 30 minutes. There was no difference in the survival period of the 2 cats in 2 of the 5 experiments, the cat without spinal anesthesia survived longer than the other in 2 of the experiments and the reverse was true in the remaining experiment. The experiments do not support the contention that a cat already in shock is benefited by the giving of a spinal anesthetic. The average difference in the weights of the traumatized

regards the length of life, since the donor lived longer than the recipient in 1, the recipient lived longer than the donor in 1, and they died at approximately the same time in another. Both the donor and recipient showed a moderate increase in the concentration of the red blood cells. The traumatized leg of the recipient was heavier in each instance than the opposite leg and in terms of percentage of body weight of the donor this difference was 1.92, 3.94, and 3.07 per cent respectively, in the 3 experiments.

Similar experiments were performed on dogs anesthetized by nembutal. There were 3 experiments, in 1 of which the trauma was repeated. The blood pressure of the donor declined during the traumatization while that of the recipient remained the same or rose. There was a moderate increase in the concentration of the red blood cells in both the donor and recipient. The traumatized animal (recipient) lived longer than the donor in 2 of the experiments and the 2 animals died at approximately the same time in the remaining experiment. The traumatized leg was heavier than the control in each instance and equalled 2.26, 3.2, and 4.8 per cent of the body weight of the donor in the 3 experiments.

In 3 experiments, the procedure consisted of traumatizing a leg which had been amputated except for the obturator, femoral, and sciatic nerves. This leg was supplied with arterial blood from a second animal by the usual technique. Chloralose was used in 2 of the experiments and nembutal in the third. The donor and recipient died at approximately the same time in the 2 experiments in which chloralose was used. The blood loss into the traumatized extremity equalled 3.6 per cent of the weight of the recipient in 1 of these experiments and was insignificant in the other. In the experiment in which nembutal was used, the donor died 2 hours following the traumatization. The blood pressure of the recipient (traumatized animal) was normal 3 hours later and the experiment was terminated.

The cross-circulation experiments were so inconclusive that it was decided that control experiments on the effects of the anemic-limb preparation should be performed.

GROUP V. ANEMIC-LIMB PREPARATIONS

These experiments were performed on dogs and cats, some being anesthetized with chloralose and others with nembutal. Six experiments were carried out on cats anesthetized with chloralose in which the effects of the anemic-limb preparation alone on the blood pressure, reflexes, and length of life were determined. The blood pressure was determined by a cannula in the carotid artery. Five of the 6 animals died in less than 13 hours after the limb had been rendered anemic, or in 13, 9, 6.5, 4, and 3 hours, respectively, an average of 7.1 hours. The blood pressure was usually at a fairly high level until shortly before death, which in several instances was fairly characteristic of respiratory failure due to anesthesia. The sixth or remaining animal was removed from the table after 24 hours in good condition, and in this cat the knee jerks did not disappear. Neither did they disappear in 4 of the 5 remaining animals until shortly before death. In the remaining cat, the knee jerks of the anemic limb disappeared 2 hours after the operation, the animal living 2 hours longer. There was a slight increase in the concentration of the red blood cells in most of the experiments.

Six experiments of the same type were performed on cats in which nembutal was the anesthetic. The length of life after rendering the limb anemic varied from 4 to 13 hours, the average being 8 hours. The length of time that the knee jerks persisted was variable. In 2 animals they did not disappear until a short time before death. A rather marked increase in the concentration of the red blood cells occurred in 3 of the 6 experiments. The high incidence of persistence of reflexes in this and the preceding type of experiment is to be explained at least partially by the fact that trauma was to have been instituted in some of them if the reflexes had disappeared. It is quite possible that the duration of life would have been greater in these cats if the blood pressure had not been determined by cannula which had to be washed out several times during the course of the experiments. In 3 additional experiments on the anemic-limb preparation in which the blood pressure was determined by needle puncture, the survival

utes, respectively, the average being 10 hours and 20 minutes. The average difference in the weights of the injured and non injured extremities equalled 2.26 per cent of the body weight. The injury in the 5 other experiments consisted of 40 blows with an iron bar. All of these animals died. The average survival period was 6 hours and 17 minutes, the individual times varying from 4 to 11 hours and the average difference in weights of the extremities equalled 3.48 per cent of the body weight. A comparison of these experiments with those in which spinal anesthesia was not given shows very little difference in the 2 groups, the survival period being slightly longer in those without spinal anesthesia.

The third type of experiment was identical with the second except that the spinal anesthesia was not given at regular intervals but was injected whenever the reflexes of the posterior extremities returned. The trauma consisted of 40 blows with an iron bar to break the femur. There were 7 experiments of this type. The blood pressure in 1 experiment remained elevated and the experiment was discontinued after 23 hours. The 6 remaining animals survived from 3 to 21 hours, the average survival period being 8 hours and 3 minutes. The average loss of fluid into the injured part equalled 3.76 per cent of the body weight. An increase in the concentration of the red blood cells was found in most of the experiments. Again, a comparison with the first or control type does not indicate that spinal anesthesia increased the tolerance to trauma.

O'Shaughnessy and Slome noted that the giving of a spinal anesthetic to a cat in shock increased the survival period. These experiments were repeated on 7 dogs anesthetized by chloralose in which shock had been produced by striking the thigh with an iron bar. The average survival period from the time of the trauma was 5 hours and 34 minutes and from the time of the injection of the spinal anesthetic was 2 hours and 33 minutes. The average difference in the weights of the traumatized and non traumatized extremities equalled 3.93 per cent of the body weight. Again, no evidence that the spinal anesthetic increased the survival time was found.

GROUP III DOGS TRAUMA, TRANSFUSION AFTER SHOCK LEVEL, WITH AND WITHOUT SPINAL ANESTHETIC

In experiments under chloralose, Slome and O'Shaughnessy found that a cat in shock as a result of trauma, if treated by the transfusion of blood and by spinal anesthesia, will survive longer than one treated by blood transfusion alone. We have performed 6 such experiments on dogs anesthetized by chloralose. After the blood pressure reached a shock level as a result of striking the thigh 40 blows with an iron bar, the femur being broken, each of the animals was given a transfusion of blood approximately equal in amount to that lost into the injured part and one half of the animals were given an injection of spinal anesthesia every 30 minutes. The dosage of novocain was the same as that used by Slome and O'Shaughnessy. The animals without spinal anesthesia lived longer on the average than those which were given novocain and the difference in the weights of the traumatized and non traumatized extremities was somewhat greater in the former group. Four of the 6 animals showed an increase in the concentration of the red blood cells and the other 2 showed no change.

GROUP IV CROSS CIRCULATION EXPERIMENTS

The procedure used was similar to that described by O'Shaughnessy and Slome. The carotid artery and external jugular vein of the donor was anastomosed to the femoral artery and femoral vein of the recipient. The anemic limb was then prepared, and following this the clips were removed from the vessels listed above, thus establishing the cross circulation. In 2 experiments on animals anesthetized with chloralose, 1 on dogs and 1 on cats, the donors lived only 2 hours following the establishment of the cross circulation and the recipients lived approximately 4 hours. The cause of death was unexplained since trauma was not instituted. In 3 experiments on dogs anesthetized with chloralose, the leg receiving the blood from the donor dog was then traumatized. The blood pressure of the donor fell during the traumatization while that of the recipient remained the same or rose somewhat. The experiments were inconclusive as

It is our impression that chloralose is a very dangerous and variable anesthetic. A number of animals were observed to die very suddenly when the blood pressure had been essentially normal a few moments before and the deaths seemed to be due to respiratory failure. This anesthetic was probably chosen by O'Shaughnessy and Slome because the reflexes usually persist after its administration and, in fact, they usually become extremely hyperactive. The cats frequently behave as though they had been given strychnine, jumping violently as a response to noise or touch. It may be that the choice of the anesthetic explains part of the discrepancy in the results of O'Shaughnessy and Slome and those of others. The cats which were anesthetized with nembutal usually maintained their knee jerks and certainly they were more nearly normal than the extremely hyperactive reflexes of the cats which received chloralose. Chloralose has much less effect on the reflexes of dogs.

Cross-circulation experiments of the type described would seem to be an ideal method by which to eliminate the factor of blood and fluid loss in response to trauma, having only the nervous factor influencing the recipient of the trauma. However, the short survival of many of the animals with an anemic-limb preparation (a necessary part of the cross-circulation experiment), particularly if chloralose is used as the anesthetic, would seem to cast doubt on the value of these studies. At any rate, our findings more nearly substantiate those of Bell, Clark and Cuthbertson than those of O'Shaughnessy and Slome. The former authors state, "By means of cross-circulation experiments it was found that trauma applied to a transfused hind limb of the recipient animal caused a marked fall in the blood pressure of the donor, followed by death within 75 minutes. The blood pressure of the recipient was practically unaffected by the injury." We have confirmed the interesting observation of O'Shaughnessy and Slome that the blood pressure of the donor falls during the traumatization while that of the recipient (traumatized animal) usually remains the same or rises slightly. This substantiates their impression that the initial fall

in blood pressure in this type of injury is due to the loss of fluid into and from the injured blood vessels. The disagreement is on the question as to why the blood pressure continues to remain depressed. It would seem that O'Shaughnessy and Slome are correct in asking the abandonment of the term, "primary shock," as applied to the early condition that follows injury to an extremity, as this and the later state are parts of one and the same picture.

In regard to the anemic-limb preparation, Slome and O'Shaughnessy state, "It was known that the onset of shock could be prevented by complete occlusion of the arterial supply of the limb prior to trauma. In this case fluid loss cannot occur; we showed that in the presence of such complete 'ischemia,' the limb is also 'anesthetic' and the nervous factor cannot operate." The results of our experiments indicate that the *anemic* limb is not entirely free of a blood supply. The moderate increase in weight with trauma suggests this. As to why most of these animals died, whether or not trauma was instituted and whether or not the knee jerks disappeared, we are unable to state. Some of the deaths were probably due to the anesthetic. It seems likely that the effective blood volume was probably decreased by the accumulation of blood in the posterior part of the body distal to the ligatures on the large blood vessels. If the reasoning of Slome and O'Shaughnessy is correct to the effect that "in the presence of such a complete 'ischemia,' the limb is also 'anesthetic' and the nervous factor cannot operate," some agency other than nervous impulses must be sought to explain the deaths.

Certainly, blood and fluid loss into and near the injured area is the most important initiating factor in the development of shock following trauma to an extremity of the anesthetized animal. After shock is fully developed, many other factors enter into its maintenance and progression. It has been shown (4) that a prolonged low blood pressure as a result of uncomplicated hemorrhage in unanesthetized animals is refractory to transfusion and results fatally. Freeman has shown that prolonged vasoconstriction produces at least part of the ill effects. Some investigators have ignored

periods were 36, 12, and 12 hours, an average of 20 hours. Nembutal was the anesthetic in the first 2 and chloralose in the last. The ligations were below the inferior mesenteric artery.

In animals in which the reflexes disappeared following the creation of the anemic limb, the effects of trauma were studied. Seven experiments were performed on cats, 4 being anesthetized with chloralose. Trauma as usual consisted of 20 blows with an iron bar, the femur being broken. The animals lived from 2 to 5 hours, an average of 4 hours. The difference in the weights of the traumatized and non traumatized extremities was small, less than 5 per cent of the body weight. A decrease in the concentration of the red blood cells was found in 2 of the 3 experiments in which it was determined. In 3 experiments, with nembutal as the anesthetic, the animals lived 4, 5, and 8 hours, an average of 5.7 hours following the trauma. All showed a moderate increase in the concentration of the red blood cells. The differences in the weights of the traumatized and non traumatized extremities were very small.

Control experiments without trauma were carried out on dogs. In 1 of the 3 performed under chloralose the aorta was occluded just below the renal arteries, and in 2 below the inferior mesenteric artery. The former animal lived 4 hours and the reflexes disappeared early. The animals with the lower ligations lived 11 and 19 hours, respectively. Reflexes disappeared in 1 and persisted in the other. An increase in the concentration of the red blood cells was found in all. In 3 dogs in which nembutal was used as the anesthetic, the aorta was occluded above the inferior mesenteric in 1 and below it in 2. The reflexes persisted in 1 of the 2 experiments in which the occlusion was below the inferior mesenteric. The animals lived 12, 16, and 16 hours, an average of 14.7 hours. A definite increase in concentration of the red blood cells occurred in 2 of the experiments.

In dogs in which the knee jerks disappeared following the anemic limb preparation trauma was applied. In 4 animals anesthetized with chloralose, the aorta was occluded below the inferior mesenteric artery in 3 and above it in 1. Following the disappearance of the re-

flexes, the leg was traumatized with approximately 40 blows with an iron bar and 15 blows with a hammer, the femur being broken. The animals lived 3, 4, 9, and 17 hours, respectively, an average of 8.2 hours. An increase in the concentration of the red blood cells occurred in 3 of the 4 experiments. The differences in the weights of the traumatized and non traumatized extremities were 0.87, 2.28, 1.8, and 1.43 per cent of the body weight, the traumatized extremity being heavier in each instance. Four experiments of the same type were done, with nembutal as the anesthetic. The occlusion of the aorta was above the inferior mesenteric artery in 1 and below it in 3, with the animals living 5, 14, 16, and 18 hours, respectively, following the traumatization, an average of 15.8 hours. A rather marked increase in the concentration of the red blood cells occurred in all. The differences in the weights of the traumatized and non traumatized extremities were .78, .77, 2.15 and .86 per cent of the body weight, the traumatized extremity was always heavier.

These results seem to indicate that the method of O'Shaughnessy and Slome does not render a limb completely anemic as evidenced by the increase in weight associated with trauma. Furthermore, the relatively short survival periods of some of the animals, particularly when chloralose was used as the anesthetic, would seem to question the value of the results of cross circulation experiments in which the anemic limb preparation is a necessary part.

EVALUATION OF STUDY—DISCUSSION

The preceding groups of experiments substantiate the views of O'Shaughnessy and Slome on the importance of the nervous factor in the production of shock following trauma to an extremity in only 1 respect, namely, that cats anesthetized by chloralose withstand trauma better if spinal anesthesia has been induced. This was not true in our experience with cats anesthetized with nembutal or with dogs anesthetized with chloralose. These latter findings held when the spinal anesthetic was administered after the shock had been induced as well as in those in which it was given before and at intervals following the trauma.

Transfusion plus spinal anesthesia was no more effective in treating this type of shock in dogs than transfusion alone. In cross-circulation experiments in which trauma was applied to a transfused hind limb of the recipient animal, no positive evidence as to deleterious effects of nervous impulses was obtained, confirming the findings of Bell, Clark, and Cuthbertson. The local loss of fluid in and near the injured area is the most important factor in the production of shock in anesthetized animals in which an extremity is traumatized. It is not maintained that this is the sole factor in the production and maintenance of this type of shock but that it is the most important one.

It has been emphasized that the mechanism of the production of all types of shock is not the same and all instances of shock cannot be explained satisfactorily by one theory. This paper deals only with the effects of trauma to an extremity of the anesthetized animal.

the part played by the loss of fluid other than whole blood. Freedlander and Lenhart state, "Rapid hemorrhage produced blood pressure curves similar in contour to those produced by trauma, however, with an equal loss of blood the end results were more severe following trauma. Further experiments showed that following trauma in addition to the loss of blood there was a considerable local loss of fluid due to edema. Therefore, the added loss of fluid could account for the more severe symptoms following trauma. This confirms the findings of Blalock." Harkins and Harmon have summarized the evidence on the effects of the loss of blood plasma.

Several interesting differences between dogs and cats were evident in these experiments. The reflexes under chloralose have been commented upon. Whereas, the red blood cells became more concentrated in a large percentage of the dogs which were traumatized a dilution usually occurred in the cat. Cats may survive after a longer period with a marked decline in blood pressure than is true with dogs. The difference in the weights of the traumatized and non traumatized extremities in percentage of body weight is usually greater in dogs in shock as a result of trauma than in cats. It is to be noted that the difference in the weights of the injured and non injured extremities in the dogs anesthetized by chloralose was not quite as great as that previously (4) found in dogs in which other anesthetics were used. Elman and Cole state, "We have observed death following the loss of 27 per cent of the body weight of a few control cats by simple bleeding from the femoral artery.

The figure obtained by Johnson and Blalock in dogs was 51 per cent. The difference in the weights of the traumatized and non traumatized extremities of cats reported in this paper was usually greater than the figure for hemorrhage obtained by Elman and Cole.

It should be emphasized that this paper is concerned only with the results of trauma to an extremity of deeply anesthetized animals. From clinical experience, it seems very likely that nervous impulses do play a part in some instances in the production and maintenance of shock following injuries. The experimental proof of this in anesthetized animals is very

questionable. It seems very doubtful if nervous impulses play as important a rôle as is ascribed to them by O'Shaughnessy and Slome. The difficulty if not the impossibility of producing shock by repeated injuries to nerves alone is well known. It is our impression that one should be very hesitant in inducing spinal anesthesia in a patient in shock as a result of trauma. None of the animals, including the cats anesthetized by chloralose, appeared to be benefited by the induction of spinal anesthesia after shock was fully developed. Holt (13) stated recently, "In the same paper O'Shaughnessy and Slome have suggested that the induction of spinal anesthesia in an animal already in a severe state of shock results in a rise in the blood pressure. This has not been our experience. In fact in severe cases of shock it appears as though the induction of spinal anesthesia hastens the fatal result. It has certainly been my experience clinically that it is a most hazardous procedure to give a spinal anesthetic to a patient who is in a state of shock or dehydration without first of all carrying out measures to bolster up the blood volume."

In concluding, it should be emphasized that the mechanism of the production of all types of shock is not the same and all instances can not be explained satisfactorily by one theory. This paper deals only with the effects of trauma to an extremity of the anesthetized animal. It has been pointed out that definite conclusions cannot be drawn from these experiments as to the mechanism of the production of shock in man.

SUMMARY

Many experiments were performed on anesthetized animals in which shock was produced by repeated blows to a thigh. The only positive evidence as to the importance of nervous impulses in its genesis was obtained in experiments on cats anesthetized by chloralose in which a preliminary and repeated spinal anesthetic apparently exerted beneficial effects. This was not found in cats anesthetized by nembutal or in dogs anesthetized by chloralose. Neither was it found in cats anesthetized by chloralose in which the novocain was not given until after shock had developed.

for it is quite possible for jaundice to become manifest in the presence of an external biliary fistula. The jaundice usually comes on, however, in from 3 to 6 months after the operation and, in a typical case, is painless in character and gradual in its onset. But there must be a wide range in the time necessary for the bile duct to become so small that all the bile cannot get through; and it is probably fair to conclude that if a patient, following a cholecystectomy, has had a normal convalescence and has remained well for a period of 2 years, any subsequent disease in the biliary ducts cannot properly be ascribed to the operation. As Carter points out, the inflammatory reaction most likely was there in an insipient stage at the time of the cholecystectomy.

Strictures which are the result of operative trauma, like those occasionally seen following ulceration about a stone, are usually local in character, while those caused by a chronic inflammatory process generally involve a considerable portion of a duct. In contradistinction to this local inflammatory lesion is the condition in which all the extrahepatic ducts are the seat of an obliterative cholangitis, and as this disease is exceedingly rare I am taking this opportunity to report a case which recently came under my observation.

Mr. K. B. H., 42 years of age, while in a mining camp in Northern Ontario in the spring of 1937, suffered an attack of what was described as dysentery which confined him to bed for 3 weeks. Some 4 months later he noticed that his skin was becoming yellow but otherwise he felt quite well, in fact, he exposed his body to the sun to hide the discoloration from his friends. During the early part of October he was in the hospital 1 week for observation and investigation and, except for the jaundice, the findings were largely negative. The liver edge could not be palpated and the stools, while not normal always, gave a positive reaction for bile. There was no elevation of temperature or pulse rate and no leucocytosis. The van den Bergh test on admission showed 52 milligrams per 1000 cubic centimeters of blood and as the jaundice was definitely fading on discharge it was thought that his was a case of infectious jaundice. During the first week in November the patient noticed that the jaundice was getting worse and he was admitted to St. Michael's Hospital on November 19, 1937, under the care of Dr. Harold Armstrong of our staff. At that time he was quite deeply jaundiced, the urine very dark, and the stools clay colored. There was, however, no enlargement of the liver and the gall bladder could not be pal-

pated. Again there was no history of pain and the temperature and pulse were normal. Exploration was decided upon and in preparation he was given calcium chloride and glucose.

At the operation, which was performed on November 24, the gall bladder was found to be normal and free from stones, but the common bile duct was about one quarter its normal size and felt like a fibrous cord. On incising it in a longitudinal direction only about a dram of pale bile came away. The wall was very thick and its lumen would barely admit a No. 4 ureteral catheter, and when the common hepatic and right and left hepatic ducts were examined, they were found to be in a similar condition. An attempt was made to drain the biliary system with a ureteral catheter but the patient went down hill steadily. Two days after the operation he ejected a rusty sputum, and this was followed a few days later by a severe secondary hemorrhage which required a transfusion. Very little bile was ever secreted and the operation site became filled with blood clots. He died of cholemia on December 7.

A somewhat similar case was reported recently by Phillips and Kilgore except that in their patient only the common hepatic and right and left hepatic ducts were involved. But their description of the findings is misleading, as the heading refers to the common bile duct so that all 3 may have been involved. No operation was performed because of the precarious condition of the patient. The diagnosis was made at the autopsy. Like the congenital variety, this is a most distressing type of obstruction and one for which little or nothing can be done.

METHODS OF TREATMENT

Many methods of dealing with a benign stricture of the bile ducts are in vogue but each stricture is an individual problem and the operator must decide upon the best procedure to adopt after a careful examination of the lesion and having in mind his own capabilities. Provided, as is usual, that the gall bladder has been removed and is therefore of no help, an end-to-end suture over a T-tube or some modification of this is best, but it is often not feasible because of the extent of the stricture, since, to be successful, there must be no tension on the suture line. Failing this the W. J. Mayo operation of anastomosing the divided duct to the duodenum is best, although because of the liability to stricture formation in the end-to-end suture, this by some is

BENIGN STRICTURES OF THE BILE DUCTS WITH A NEW METHOD OF TREATMENT

GEORGE EWART WILSON, M B, I R C S, F A C S, Toronto, Ontario

BENIGN strictures of the bile ducts are among the less common causes of obstructive jaundice, but they constitute the most difficult problems in gall bladder disease which surgeons are called upon to treat, for unless the flow of bile is directed freely into the intestinal tract the patient has nothing to look forward to but a miserable existence ending eventually in death

CAUSES OF STRICTURES

In addition to the congenital variety, which is fortunately rare, there are 3 causes of benign strictures of the bile ducts injury to either the common hepatic or common bile duct at the time of the cholecystectomy, ulceration with subsequent cicatrization about a stone in the duct, or inflammation in the ducts quite apart from the presence of a stone

Injury at a previous operation, however, is by far the most common cause Walters, at a staff meeting of the Mayo Clinic, reported 51 operations for stricture of the bile ducts and draws attention to the fact that in every instance there had been a previous operation upon the biliary tract, all but 3 having had a cholecystectomy Lahey, who at the time of his paper on strictures of the common and hepatic ducts had operated upon 37 patients, expresses the same opinion There are several ways in which the ducts may be injured and these are well exemplified in Lahey's article The only safeguard, however, is visualization of both the common hepatic and common bile ducts before either the cystic duct or artery is tied, having in mind various abnormalities, especially the presence of a long cystic duct which is adherent to the common hepatic duct for an inch or so before joining with that structure to form the common bile duct Recently, in operating upon the biliary tract, I

found the hepatic artery crossing in front of the entrance of the cystic duct and then continuing on into the hilus on the right side of the common hepatic duct, where for a time it was thought to be the duct, so it behooves the surgeon always to take a second look and be sure

But, while it is true that the great majority of benign strictures are the result of faulty technique in removing a gall bladder, the surgeon is not always to blame Aynesworth reports the case of a woman whose gall bladder was removed 2 months after a cholecystostomy and the patient remained well for 7 years She then returned with all the signs of an obstructed common duct which at operation was found to involve about an inch of the proximal portion of the common bile duct Certainly in this instance the cholecystectomy cannot have been the cause which must be attributed to *cholangitis* There are many instances in the literature of the stricture developing or at least showing itself 2 or 3 years following the removal of the gall bladder In fact, Judd was strongly of the opinion that an obliterative *cholangitis* was responsible in a large number of cases Be this as it may there is one infallible sign that the operator has been at fault, that is the prolonged drainage of bile from the operative wound, a complication which was a marked feature of the case which I am to report

The history of difficulty in controlling hemorrhage from the cystic artery, as pointed out by Lahey, is also of the greatest significance, and hurried attempts to secure the bleeding vessel without first obtaining a dry field are responsible for the many instances in which the common hepatic duct is injured The time of the onset of the jaundice depends upon the extent of the injury to the duct, upon the consistency of the bile, whether thick or thin, and whether or not all the bile is being discharged through the abdominal wall,

Then again, instead of acting as a channel the tube may actually be obstructing the flow of bile, as shown by the prompt relief sometimes seen following the evacuation of the tube which may even be vomited. There are recorded instances of a tube causing intestinal obstruction and Roeder, apparently in a personal communication to Eliot, refers to a case in which a long tube in a biliary fistula implantation perforated the sigmoid causing a fatal peritonitis 3 months after insertion. Most surgeons then would probably agree with Lahey that this method is at best only a makeshift.

Another way in which these difficult strictures may be treated is by the Wilms-Sullivan method. This consists of inserting a tube of suitable size into the proximal part of the duct and the distal end into the duodenum and then covering the exposed portion of the tube with omentum. Ellsworth Eliot, Jr., whose remarkable contributions to the subject of benign strictures of the bile ducts are of outstanding merit, and from which I have drawn freely in preparing this paper, has with commendable zeal and energy collected 38 cases in which this type of repair was employed. Thirty-five of these are reported in his 1936 article, together with 3 others, those of Brewer, Terrier and Propping which were omitted from his collection in *SURGERY, GYNECOLOGY AND OBSTETRICS*, published in January, 1918.

An analysis of these cases is most instructive. Of the total, 5 are reported by Wilms and his associate Brandt and there was no mortality, but in none was the elapsed time sufficient to properly appraise the result. Two of the patients developed a duodenal fistula, 1 so severe as to require a jejunostomy and the other required a second operation for its relief. In a third case the operation had to be repeated. Jenckel has had the best results from this method. He has had 10 operations to his credit with only 2 deaths, 1 of which, however, did not occur until 12 years later and from the description death in this instance was undoubtedly caused by a liver ailment. Altogether there were 11 deaths or a mortality rate of approximately 29 per cent.

If Wilms' and Jenckel's cases are omitted, which would give a more accurate cross section of the death rate from this operation, the mortality rate approximates 39 per cent. In many of the reported cases important details are lacking but recurrence of the stricture is common together with cholangitis, biliary and duodenal fistulas, and abscess of the liver. In this connection it is interesting to note, as emphasized recently by Sandblom, Bergh and Ivy, that following any abnormal channel between the biliary and intestinal tract hepatitis and liver abscesses are of frequent occurrence, and, peculiarly enough, they give little clinical evidence of their presence and are discovered only at autopsy. But it is not in the nature of things for surgeons to be eager to report their failures, so there must be a considerable number which are not recorded. It would appear, however, that sufficient evidence has been collected to show that the Wilms-Sullivan operation leaves much to be desired.

Another method by which these difficult strictures can be treated is to allow a biliary fistula to form, wait 3 or 4 months and then cone out this track and implant it into some portion of the gastro-intestinal tract. The operation, however, is by no means a simple one for, unless an adequate blood supply is provided, the fistulous track will die, and even if this difficulty is overcome, undue tension will have the same effect so that it is not to be wondered at if failures are frequent occurrences.

Again we are indebted to Eliot for his collection of 41 cases, the majority of which are from surgeons in this country. In 22 the implantation was into the duodenum, in 18 into the stomach, and 1 into the jejunum. Here, too, some of the reported cases were too recent to evaluate the result, but there were 18 in which death could be attributed to the operation making a mortality rate of about 45 per cent. Hemorrhage, shock, and hepatic insufficiency account for many of the early deaths, but if the patient survives the operation there are many complications which may supervene. Nine of these patients are reported to have developed strictures and in one instance this occurred a second time, so that

considered the operation of choice. Provided the stricture is below the entrance of the cystic duct, this is not a particularly difficult procedure to one accustomed to gall bladder surgery, but to the inexperienced it may be a hazardous operation especially as is the case when a long and tedious dissection is necessary before the exact condition of the ducts is demonstrated. But if the stricture extends high up in the common hepatic duct, it may be quite impossible or even highly dangerous, particularly in a fat subject or when dense adhesions prevent the duodenum from being mobilized sufficiently to permit accurate anastomosis without tension. It is to benign strictures of this kind in which neither end to end suture nor some form of direct anastomosis between the dilated duct and the gastro intestinal tract is feasible, that I wish particularly to direct attention in this paper.

Several methods, many of them very ingenious, have been employed in an attempt to establish a connection with the intestinal tract. One plan is to incise the stricture throughout its length and, after making sure that the distal portion of the duct is open to the duodenum, to connect the two ends with a rubber tube of suitable size and length and to suture the adjacent tissues snugly over it. Some prefer that the tube be passed through the ampulla into the duodenum, while others advise that it should stop short of the bowel. If it is the intention to have the tube remain *in situ* or to remove it once it has served its purpose, it should not pass through the ampulla, for there is abundant evidence as shown by Sandblom, Bergh, and Ivy, that the danger of infection spreading up the duct is increased by any interference with the function of the sphincter of Oddi. And under such circumstances there is danger not only of a biliary fistula but, what is much more important, a duodenal fistula as well. But passing a tube through the ampulla of Vater is by no means the simple procedure which a perusal of the literature would lead one to suppose. It may in fact be quite a difficult feat and, if the inside of the duodenum were examined in every instance, not a few would be found to have entered by a false passage as may be verified by a perusal of autopsy findings. Of

course, if the ampulla can once be entered for sure by some form of bougie, dilatation to the requisite size is readily accomplished, but in a small percentage of cases there is always a reasonable doubt about where the instrument has gone.

Leaving a rubber tube in a bile duct has many disadvantages and, as Lahey contends, is at best nothing more than a makeshift. It may pass too quickly before time has been afforded for reconstruction of the channel, and to obviate this difficulty McArthur puts a reverse cuff on the end of the tube. On the other hand, it may remain too long, for it is probably true that if it does not pass it will sooner or later give rise to trouble. Naturally, the more normal the bile flow is in consistency the longer will the symptom free period be, but incrustations both within and without the tube are almost inevitable and they may actually block the flow of bile. Colp, however, states that many tubes which have apparently been in the ducts for almost a year show very little deposit of bile salts, and he is most insistent that the greatest care be exercised in selecting the best and highest grade of rubber and, if possible, a variety that is opaque to the x rays. Judd removed a calcified tube in one case 4 years and in another 6 years after its insertion, the patient in each instance suffering from a severe attack of cholangitis. But Lahey, in the excellent article already referred to, treated one of the strictures by this method and made reference to removing a tube, for what he does not say, which had functioned well for 7 years and which he replaced by another.

But there are other objections to the indwelling tube, whether its distal end projects into the duodenum or not. It may become displaced upward so as to lie in the hilus of the liver, as in a case recently reported by Robert L. Payne. When used in an end to end suture, the tube has been known to become angulated at the suture line with the production of a biliary fistula, and to obviate this, Voelcker advocated bringing the tube out through the duodenum by the Witzel method, but this merely substitutes the danger of a duodenal fistula for the biliary one, although in a reported case the result was most gratifying.

The new method which I wish to record is in reality a very simple procedure and consists essentially of making a new bile channel out of the wall of the stomach but without opening it. The exposure of the ducts, a tedious, difficult, and dangerous procedure at all times, is made in the ordinary way. If the operator decides that an end-to-end suture is impossible or an anastomosis of the proximal end to the duodenum is not feasible, one proceeds as follows: After isolating the dilated portion of duct which will likely be found high up in the hilus of the liver, and making sure of its identity by aspiration with a hypodermic needle, the operator slits it sufficiently wide to admit a tube about the size of a No 20 French catheter which is immediately inserted and the opening closed tightly around it by a suture. The tube is then placed upon the anterior surface of the stomach commencing just proximal to the pylorus and buried for a distance of 2 inches in its wall by oversewing with a running stitch of catgut. Omentum is then tucked about the exposed portion of the tube that lies between the bile duct and the stomach after which the free end of the tube is brought out through the upper portion of the abdominal incision, where it is securely fastened by a silkworm stitch and the abdomen closed (Fig. 1).

Our original conception was to withdraw the tube in about 3 months when it was thought a new channel would be well established. It would then be a simple matter to insert an internal urethrotomy knife the requisite distance, cut through the wall and produce an internal fistula, but to our surprise nature, apparently by a process of ulceration, had accomplished this for us. Following this the external opening promptly closed.

CASE 1. Mrs. M., 26 years of age, having suffered repeated attacks of colic with jaundice, was operated upon by another surgeon on September 21, 1932. The gall bladder containing 1 moderately large stone was removed and, although the common bile duct was not dilated and there was no jaundice at the time, the ducts were examined by passing a lead probe through the stump of the cystic duct split to admit the probe. The probe is said to have entered the duodenum and no stones were found. The next day there was a profuse flow of bile mixed with blood from the wound and this was the precursor to a very stormy time. The bile continued to

Fig 1 Diagram showing tube entering the bile duct, bridging the gap to the region of the antrum where it is embedded by the Witzel method and then on to the abdominal incision

be discharged from the surface and by the middle of October the stools were clay colored. In spite of the external biliary fistula she commenced to get jaundiced about the middle of November and by the end of the month it was very marked. On December 3, 1932, I operated upon her hoping to find a stone, but after a tedious dissection no trace whatever could be found of the common bile duct, and the stump of the common hepatic duct appeared as a grape-like projection in the hilus of the liver. One limb of a T-tube was placed in the duct and the other into the duodenum while the stem together with a Penrose drain was brought out through the abdominal incision. In a few days, although the stools were bile stained, she developed a very severe type of duodenal fistula so that very soon much of the food she consumed together with a large quantity of bile was discharged through the wound and she lost weight quite rapidly. She went through a very trying period but after a couple of months she commenced to pick up and she was discharged on March 3, 1933, with the T-tube still in place. She had no jaundice at this time but there was still a small quantity of duodenal content coming away alongside of the T-tube. She enjoyed tolerable health until August when she began to have frequent attacks of pain and jaundice so the T-tube was removed. No improvement followed and by the end of October the external fistula had closed. On December 14, 1933, she was re-admitted at which time she was deeply jaundiced with clay colored stools and very much underweight. On December 20 I operated on her again and after a most difficult dissection isolated the proximal portion of the duct and performed the operation described. Her convalescence was quiet and uneventful. Bile discharged freely from the tube and the jaundice rapidly cleared. She was discharged on February

in these cases another and obviously much more difficult operation had to be performed in order to relieve the individuals of their distress. Lahey has operated on 14 patients by this method, 7 of which are recorded in Eliot's list, and concludes that in only 2 instances was there permanent benefit, most of the survivors having fared badly because of contraction of the fistulous track. One of his patients, however, was well 15 years after the operation. But Walters, who has performed this operation 9 times, 7 of which are in Eliot's list, expressed the opinion that it continues to be a useful procedure. One of his patients was symptom free 9 years after the operation.

According to personal communications to Eliot, the German surgeons also were having trouble with the direct method of implantation. Hildebrand in an attempt to obviate the bad results divided the upper jejunum and, after re-establishing the continuity of the intestinal tract, brought the distal end out through the abdominal wall for anastomosis to the opening on the skin of the biliary fistula. His patient died, however, 5 years later with deep jaundice and a subhepatic abscess. Other German surgeons modified this procedure but with no better result. Nevertheless, in spite of the few brilliant results which have been obtained by direct implantation of the fistulous track, it must be obvious to all that any operative measure, which in the hands of experts carries such a high mortality, must be undertaken with a considerable amount of misgiving. Most surgeons would probably agree with the statement of Vincent, as quoted by Eliot, that a partial result which begets cirrhosis is not worth while.

Another way in which these difficult types of stricture have been dealt with is by direct anastomosis of the liver substance to some portion of the intestinal tract usually the duodenum. This operation is known as hepato enterostomy. Eliot has succeeded in collecting 11 cases all from German sources and mostly by personal communication, but as far as I can learn there is no report of a similar procedure having been done in this country. It is performed by puncturing the liver with the actual cautery in an attempt to

establish a biliary fistula, and subsequently dissecting this out and implanting it into some portion of the intestinal tract, or the punctured liver may be immediately anastomosed to the intestine. That bile may flow quite freely from a liver fistula is attested to by many authors. I recall a jaundiced patient in whom a copious discharge, which lasted for nearly 4 weeks, followed the incision of a necrotic area in the left lobe of the liver. It had, however, very little effect upon the icteric index and eventually closed leaving the patient no better off than before. Granulation tissue encroaches more and more upon the lumen and though it may be kept open for a while by curetting, the tissue usually wins out in the end. Enderlen's patient, who was alive and well 11 years afterward, is assuredly a brilliant result, but Enderlen also reports a second case in which the same technique was used, following the failure of a previous hepatoduodenostomy, and the patient died about a week postoperatively. At the autopsy the original anastomotic opening was found to be completely obliterated. But in Lameris' patient, who died 8 months after the operation from multiple abscesses of the liver, there were 10 small openings in the liver at the anastomotic site from which bile could be expressed. Undoubtedly there is a considerable variation in the distribution of the large bile ducts within the liver.

Any considerable discharge of bile from the liver in doing a cholecystectomy is unusual, but some years ago I opened up a bile duct fully an eighth of an inch in diameter about $1\frac{1}{2}$ inches from the anterior border of the liver, and so freely did bile flow that it was thought at first to be coming from an injury to one of the main ducts. For 2 weeks the discharge of bile was fairly free after which it gradually ceased and the wound was closed within a month. It would appear then that there is a considerable element of luck in selecting the area of liver to be joined to the bowel. It does not, however, strike one as a feasible way in which the bile may be successfully drained into the intestinal tract, and the fact that it has not been taken up by any surgeon in this country is probably sufficient to indicate that it has little to recommend it.

CANCER OF THE STOMACH

W. H. OGILVIE, M Ch , M D. (Ox), F.R C.S. (Eng.), London, England

WE may find cause for satisfaction in the general advance of surgery during the last decade, but upon the subject of cancer of the stomach we can look only with gloom. It is the commonest of all cancers, and though its incidence varies in different countries, it, nevertheless, occupies this unenviable predominance. The operability in cases of patients presenting themselves with symptoms is lower than with any other growth. The operative mortality remains much as it was 30 years ago and is the highest of any major operation. The cure rate among those that survive is the lowest in cancer surgery. Yet no alternative treatment that might relieve us of this depressing and almost hopeless task has appeared on the scene. I have chosen to present this unsatisfactory subject because I consider that in endeavoring to set our house in order we ought to pass by its beautiful chambers, many of them recently renovated and re-decorated in the latest style, and turn our attention to the dreary basements. I shall make suggestions as to how we should set about this task, but I shall not present my own figures, which are too few to be impressive and too true to be good. I may, however, illustrate the position today by a simple diagram, constructed from the figures of many surgeons of experience and repute (Fig. 1).

Gastric cancer thus presents a four-fold problem for attack. It is the commonest and least operable of all growths, and its treatment by surgery has the highest death rate and the lowest cure rate. If any of these aspects can be tackled successfully, we shall be doing something to better the present position; and they can all be tackled. We know that the disease is commoner in certain countries, in certain areas in those countries (Fig. 2), and in those areas it is seen most often in men of certain occupations. It should not be beyond the power of statisticians to trace

the factors that are responsible for this incidence, or of public health authorities to eliminate them.

The low operability rate is a reflection upon our diagnosis. Many sufferers from cancer of the stomach have no warning beyond an indefinable loss of strength till nearly the whole organ is involved; but on the other hand many of those who arrive, to our chagrin, far too late, have suffered from digestive discomfort for months or even for a year or 2, and have had recourse to diet and alkalis before finally coming to their physician for an overhauling. Should we not write up in neon lights in every restaurant, "Indigestion does not start after 40 in a man who has been able to eat anything till then." Should we not even put a more discreet notice in the office of our medical colleagues, "Gastric ulcer does not present itself for the first time after 40." Both statements are obviously open to exceptions. But if we make it a rule that every case of indigestion, starting in middle life, be immediately investigated to eliminate cancer before any treatment is undertaken, and if we label every gastric ulcer first appearing after 40 as malignant, until unequivocal appearance in the gastroscope, or rapid disappearance of the deformity in the roentgenogram and of occult blood from the feces have shown it to be innocent, we shall immediately bring a large number of patients from the hopeless into the hopeful category. It is, however, with the last two aspects, the high death rate and the low cure rate that we, as surgeons, are particularly concerned.

To discuss mortality implies setting a figure, just as to discuss a golfer's handicap implies fixing bogey for the course. Among good surgeons I would put the hospital death rate between 20 and 30 per cent after operations for cancer of the stomach. I am aware that figures of 10 per cent and under have been recorded, but knowing what I do of the limits of technical skill, I cannot believe that they all refer to the same thing. A few gastric

11, 1934, with instructions to keep in touch with our outdoor department. In my absence arrangements were made on March 22 to produce an internal fistula but after a few whiffs of ether she vomited up bile and the operation was not proceeded with as it was obvious an internal fistula had already been established. Following this no bile or stomach content came from the abdominal wound and the opening was closed in 2 weeks. She has never had an attack of jaundice since and when seen recently looked in perfect health having gained 40 pounds.

One of the great advantages of the operation herein recorded is that it is a simple procedure and one that may be quickly carried out. Most patients by the time the ducts have been clearly visualized, are in no condition to undergo any further difficult procedure hence the advice of some surgeons to permit the formation of a biliary fistula and do a second operation later. Since the stomach is not opened at the time there is no possibility of peritonitis or a dangerous fistula. Obviously, a single case in which the patient has been well for nearly 5 years is not sufficient to permit one to make extravagant claims, and stricture and cholangitis, the bugbears of bile duct surgery, may yet supervene unless per chance the endothelial cells from the peritoneal coat of the stomach be more effective in producing a protective lining than the epithelium has been in some other types of reconstruction. But complications will probably occur even after most successful reconstructions of the ducts if there is a sufficiently long survival and a proper follow up is instituted.

CONCLUSIONS

Most benign strictures of the bile ducts follow a cholecystectomy and an unexpected flow of bile from the wound a day or so after ward or a stormy convalescence is very significant.

Diffuse narrowing of the ducts is a rare variety and a case is recorded.

End to end suture or direct anastomosis of the duct to the duodenum is the operation of choice when this can be accomplished without tension.

The difficult cases, however, are those in which these methods are impossible and it is with this type that the paper largely deals.

The disadvantages and difficulties of reconstruction over a buried rubber tube are outlined. The Wilms-Sullivan operation and the implantation of the biliary fistula into the gastro-intestinal tract are shown to be unsatisfactory and accompanied by a very high mortality. Direct anastomosis of the liver substance to the bowel is a method which has been used by continental surgeons only and is not to be recommended.

A new method which is simple and safe for dealing with these difficult strictures is recorded and details of a successful case are given.

successful in some 250 gastric resections, and that the number in which it has had to be supplemented by gas is only about a dozen.

Premedication is necessary because no normal person can lie still for 1 to 2 hours on a narrow and rigid table unless so prepared. Basal narcotics are unsatisfactory for this purpose, for they make the patient a reflex animal bereft of higher control, and he responds to all stimuli by movement. After

many experiments I have adopted the use of omnupon two-thirds of a grain 1 hour before operation. Two adjuvant drugs should be avoided: atropine, because the thirst it induces makes the patient restless, and hyoscine because, though it quiets some patients, it makes others silly drunk and quite uncontrollable. After the omnupon is given, the patient's ears are plugged with wool and his eyes covered. He is brought to the theater

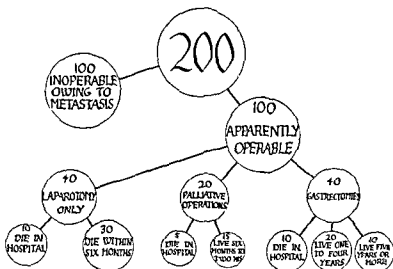

Fig. 1 The fate of 200 cases of cancer of the stomach presenting themselves at hospital

ulcers slipped in by a lenient pathologist will do wonders for any series

In the hands of expert surgeons, patients do not die of gastrectomy. Shock has been abolished and hemorrhage does not occur. Speed without haste and neatness without fuss ensure that patients leave the table little the worse for their ordeal. But patients die after gastrectomy because those with cancer of the stomach are old, enfeebled, and liable to die at any time so that they often succumb while they are in the hospital for investigation or are undergoing palliative treatment. Nevertheless, we must remember that in the operation for cancer of the stomach we are working pretty near the limits of human endurance, and if we are to improve our late results we must push right up to those limits. Whatever of speed, dexterity, and gentleness we have learned from the great masters like Halsted and Moynihan we must put into practice.

To those technical details I would add one further that to my mind is essential, the use of local anesthesia. However good a surgeon's mortality may be it will be better if he adopt this method. Local anesthesia will make the operation easier for the surgeon, and this leads to neater and quicker work, but it also removes all need for hurry, should extra time be wanted for some refinement. Relaxa-

tion is perfect, respiratory movements are slow and shallow, the blood pressure is not raised nor the capillaries dilated, and the viscera preserve their tone and movement and do not prolapse from the wound. It abolishes many of the risks of the postoperative period. The patient is conscious and rational, unlike the subject of spinal anesthesia, he can sit up, he can breathe, move, and drink, so that the likelihood of respiratory, vascular, and embolic complications is greatly diminished. Further he has inhaled no foreign vapor or gas, so that he will not secrete respiratory mucus in excess. These advantages continue over the later stages of recovery, for the solution employed, introduced by Crile for anoci association is anesthetic for 4 hours at any rate and diminishes painful sensations for several days tiding over the patient to the stage of repair. The inhibition of a painful wound is avoided.

I hesitate to describe my method knowing that the use of local anesthesia is associated above all with the name of Hans Finsterer, to whom I owe more than I can say. But since I had the opportunity of seeing him do only 2 cases, and used the method 7 years before and 6 years since that time, I cannot say how far my present technique corresponds to his. I can only say that it has proved entirely

Fig 6. Relations of the splanchnic plexus

Five wheals are necessary, 1 just below the xiphisternum, and 2 each side of the outer border of the rectus in the subcostal and inter-spinous planes (Fig. 3). A very fine needle is used, and after each wheal is made the needle is pushed on into the rectus sheath in several places by sliding the skin, injecting a few cubic centimeters in each, so that sheath and muscle are made insensitive to the larger needle that follows. The whole operation should be painless except for the first 5 pricks.

The next step is to inject the subcutaneous tissues in a fan over the xiphisternum and lower costal cartilages. This area is not insensitized by a rectus sheath block, yet it adjoins the upper end of the incision and may easily be touched by a sharp instrument. An injection of 15 cubic centimeters of one-half per cent solution is used for this. From the same central wheal an injection of 5 cubic centimeters is put into the rectus sheath on each side of the xiphisternum.

A continuous puddle of one-half per cent solution is now laid along the costal margin and outer border of the rectus, to infiltrate the nerves where they lie as single trunks in an aponeurotic compartment. The solution

is injected through the 2 lateral wheals into a sheath already anesthetized, and is distributed as evenly as possible, about 5 cubic centimeters to the inch, or 70 cubic centimeters each side. The operator washes up again, putting on his gown and gloves, and returns to find everything ready, and the patient probably asleep.

After the peritoneum has been opened, the wound edges are held up by an assistant, and further injections of one-half per cent solution, or 20 cubic centimeters on each side, are made from within, chiefly into the diaphragmatic peritoneum and the right and left paracolic gutters (Fig 4). These are areas that have not been anesthetized by the rectus sheath block. A broad and deep retractor is then slipped under the liver and held back by an assistant, while the surgeon places his right hand, palm downward, on the stomach and slips the tips of his fingers down the retractor till they rest on the aorta (Fig 5). The middle finger identifies the aorta above the celiac axis trunk by the fact that no pancreas intervenes, and then pushes it to the left, increasing the normal space of about half an inch between the aorta and vena cava to 1 inch. The splanchnic injection is made into

Fig 3

Fig 4

Fig 3 Local anesthesia of the abdominal wall (1) cutaneous wheal (2) subcutaneous injections, (3) deep injections

Fig 4 Supplementary injections into the abdominal parietes from within

some minutes before the surgeon is ready, and encouraged to doze off on the table

The anesthetic solution is made in two strengths (1) novocain, one half per cent, quinine and urea hydrochloride, one fourth per cent, Ringer's solution to 400 cubic centimeters, (2) novocain, one per cent, quinine and urea hydrochloride, one fourth per cent, Ringer's solution to 60 cubic centimeters To

each solution 1 drop of adrenalin for every 10 cubic centimeters is added just before use

I use the Labat 10 cubic centimeter syringe, 2 of which are alternately handed to me, filled by the assistant. Regional block is not tissue infiltration but measured dosage at certain anatomical points, and with pressure apparatus or self feeding, syringes this ideal is lost sight of. I regard it as important that no local anesthetic be injected into any tissue that is going to be cut or handled, if this can be avoided, so that the whole operation, dissection and subsequent suture, takes place as far as possible in normal tissues. For this reason I have abandoned infiltration of the line of incision

Fig 5 Injection of the splanchnic plexus

Injection is done before gown or gloves are put on 2 temporary sterile towels being put above and below the operative field. This plan enforces a delay of 5 minutes while the surgeon is dressing up, which allows the patient to settle down to sleep, gives the local anesthetic time to take effect and affords the nurse and assistant an unhurried interval to repaint the abdomen, drape the field, and rehearse every detail of instruments and material before the operation starts

Fig 9 The peritoneal compartments in relation to cancer spread 1 Celomic transplantation of gastric cancer, 2, amount of cancer bed removed in standard gastrectomy, 3, amount removed in radical gastrectomy

it is not often that the otherwise early and operable case is taken out of that category on these grounds

The sinister features of cancer of the stomach are its wide and early dissemination by lymphatic channels, and its tendency to shed cells that graft themselves on the peritoneum, usually on the omentum or in the pelvis. The cases that seem from their histories to be early and from the skiagrams to be localized but prove on laparotomy to be inoperable, are usually hopeless because of wide dissemination in lymphatic channels or distant peritoneal deposits. Those that recur after an apparently adequate resection do so either in the upper part of the stomach and the glands round the celiac axis, or in distant parts of the celomic cavity. Such recurrences are, of course, the development of extensions that were present but imperceptible at the time of operation, for cancer never recurs. We have here a problem with which we, as surgeons, can rightly concern ourselves while we are waiting for our medical friends to send us earlier cases, and that is the extending of our operation as far as is technically possible to embrace the whole area in which malignant cells are likely to lie in the early and apparently operable cases of gastric cancer.

We cannot, by any means within the compass of practical surgery, remove all seedlings of cancer that may have been cast into the peritoneal cavity. But the earlier free cells, if shed from the anterior surface of the stomach, are likely to lie in that part of the cavity bounded by the anterior abdominal wall in front, and the great omentum behind, and if arising from the posterior surface of the stomach, they will drop into the lesser sac, bounded to a large extent by the omentum and transverse mesocolon (Fig. 9, 1). Removal of the whole great omentum with the stomach, by detaching it from the colon and following this plane down the superior leaf of the transverse mesocolon to the posterior abdominal wall, will remove about 75 per cent of this potential cancer bed (Fig. 9, 3). This step, which on technical grounds simplifies the operation of gastrectomy very considerably for no vessels are cut in this dissociation of embryologically fused structures, is not recommended in gastrectomy for ulcer. The latter should be kept as conservative as possible. In gastrectomy for cancer it is the first essential of a radical operation.

In planning the adequate removal of lymphatic tissues, we have before us that prototype of well planned and successful cancer surgery, the Halsted operation for cancer of

Fig 7 The author's needle for splanchnic anesthesia

the retroperitoneal tissue in this gap, that is, into the right crus of the diaphragm where it lies on the first lumbar vertebra (Fig 6). To do this safely it is necessary to have a guarded needle that can be slid along the finger till it rests on the vertebral body without tearing the glove, or injuring the liver or any vessels in the lesser omentum. Sixty cubic centimeters of the 1 per cent solution are injected slowly and diffusely round the splanchnic plexus.

The needle I have designed consists of three parts: the needle itself, the sheath and a sheath (Fig 7). A stud on the collar of the needle can engage in a slot in the sheath in the first position; the point is bud and the sheath forms a safe blunt instrument of exploration. In the second position the point protrudes half an inch and pierces the peritoneum covering the splanchnic plexus.

Fig 8 Mesenteric injections to supplement the splanchnic anesthesia

I supplement this splanchnic injection by a few further mesenteric injections of one half per cent solution, a modification I learned from Finsterer (Fig 8). Ten cubic centimeters are injected into the highest point of the 1 cc curve, 10 cubic centimeters into its lowest point, 5 cubic centimeters between the duodenum and hepatic flexure and 10 cubic centimeters into the base of the transverse mesocolon, where the middle colic leaves the superior mesenteric artery. The extra injections make doubly sure that the stomach, duodenum, transverse colon, and jejunum are insensitve, but I believe their chief value is to occupy a few minutes during which the splanchnic injection is taking effect, and to give the surgeon confidence. The combination of splanchnic and mesenteric injections is so harmless and so uniformly successful that I have never felt tempted to go back to splanchnic injections alone.

The present cure rate, judged on the 5 year standard, is from 5 to 10 per cent of all cases operated upon. If the inquiry is limited to cases suitable for gastrectomy, the cures increase from 15 to 17 per cent and if only the patients having had gastrectomies and leaving hospital alive are considered, the rate rises to 20 and 25 per cent. Even so this figure is one that no surgeon can view without a feeling of profound dissatisfaction. A discussion of the means whereby the cure rate may be improved involves consideration of how the disease spreads and where it recurs.

Cancer spreads by 4 main routes: by direct extension by the blood stream, by lymphatics, and by dissemination of cells on a free surface. Many cancers of the stomach, when we first see them, are inoperable for 1 of the first 2 reasons, because the growth has invaded neighboring structures too widely for removal or because the liver contains secondary nodules. But these are usually late cases, and

Fig 13 Ligature of the right gastro-epiploic artery at its origin

These glands drain the lymphatic plexuses in the submucous and subperitoneal coats of the stomach wall, in which cancer cells are usually found at some considerable distance from the parent growth. The whole stomach could be removed in every case, on the analogy of breast surgery, but total gastrectomy carries a high mortality, one that is never likely to be greatly reduced. It is due to the unsuturable qualities of the esophagus, and

Fig 14 Author's method of duodenal invagination

could hardly be justified by any improvement in the cure rate that is in sight. Section of the stomach wall 4 inches beyond the palpable edge of the growth is in most cases sufficient to get beyond the extensions in the lymphatic plexuses, and when cancer cells have got beyond this distance they have probably got beyond removal even by the most radical surgery. On the duodenal side

Fig 15 Exposure of the left gastric artery at its origin from the celiac axis trunk

Fig 16 The operation completed

Fig 10 Simplified schema of the arteries and lymphatics of the stomach

Fig 11 Opening the fusion plane between the omentum and transverse colon

the breast. In this operation, the growth, the organ in which it arises, the lymphatic channels which drain that organ, and the glands into which those channels empty, are removed in one piece. We start in the axilla, stripping the main vessels clear of all areolar tissue, tying all arteries and veins at their junction with the main trunk, leaving axillary vessels and brachial plexus bare, and bringing down

the whole mass of fat and glands to be removed with the breast. A radical operation for gastric cancer implies that the vessels are similarly divided at their junction with the parent trunk, and that the whole lymphatic tract that accompanies them is removed with the stomach.

Two vessels only are important in this respect, the right gastroepiploic artery and the left gastric artery (Fig 10). The left gastroepiploic is small and far from the cancer area, and the right gastric is in most cases represented by a leash of vessels that supply the duodenum. The right gastroepiploic arises from the gastroduodenal in the groove between the duodenum and pancreas, and along it are grouped the glands into which the lymphatics of the greater curvature drain. The left gastric is a large artery that springs from the celiac axis just at the upper border of the pancreas, not much above the mid point of the lesser curve of the stomach. After a short course as a trunk it breaks into a number of branches, that spread in a fan to supply the upper border of the stomach from the cardia to the pylorus. The interval between these branches, and between them and the stomach is filled with fat and the lymphatic glands draining the lesser curve. The whole, artery, glands, and fat, is enclosed in a double fold of peritoneum, passing from the posterior abdominal wall to the lesser curve of the stomach, that often includes lobules of pancreas as well.

Fig 12 Freeing the omentum and superior leaf of transverse mesocolon from the colon and mesocolon proper

phatic clearance has been adequately performed, so that the aorta and intercrural fibers of the diaphragm are left bare, the splanchnic plexus is also resected in its upper part. I have not observed the cases sufficiently long to have established a regular clinical picture, but all in whom the removal of perigastric tissues has been radical have run a similar course. For the first 24 hours after operation they have been in excellent condition. After that they have shown abdominal distention, constipation, and vomiting of any fluids given by mouth. Flatus was voided, and some subjective relief experienced after enemas, but little fecal matter was passed

and the distention increased rather than diminished. With intravenous administration of glucose in water, together with prostigmine and acetyl choline at regular intervals, and ox bile enemas night and morning, the vomiting ceased, and the distention slowly subsided, but it has been nearly a fortnight before the abdomen reached its normal contour.

This operation does not introduce any new principles, but it attempts to carry gastrectomy for cancer to its logical conclusion, and to bring it into line with the operation for cancer of the breast. It should, therefore, add to the number of those who are permanently cured of this dread disease by surgery.

the dictum that cancer never spreads beyond the pylorus is as true as most aphorisms, cancer rarely spreads there, but if we examine the duodenum in all our specimens we will find a few in which the wall shows permeation for a short distance. It is, therefore, necessary in an operation that aims at being radical to remove a full inch of duodenal wall with the stomach.

The radical operation for cancer of the stomach may then be outlined briefly as follows. After the abdomen has been opened and the question of operability settled by careful examination and palpation, the assistant holds up the transverse colon to the limit of its mesentery, and the surgeon, extending the great omentum with his left hand, runs a sharp knife along the bloodless fold, now on the stretch, that unites the omentum to the colon (Fig. 11). He carries this dissection right down to the hepatic flexure, following the omentum to its absolute termination on the right, and on the left to within 2 inches of the splenic flexure. With a moist swab he then pushes the omentum upward, when it will separate from the transverse mesocolon, carrying the omental vessels and the posterior peritoneum of the lesser sac with it, until the ridge of the pancreas is reached (Fig. 12). On the right this separation brings the right free margin of the omentum, carrying the main trunk of the gastropiploic artery, off the head of the pancreas, where it can be tied as a single trunk (the only ligature that has yet been needed) as it leaves the gastroduodenal artery, a point beyond any recognizable glands of the greater curvature group (Fig. 13). The right gastric vascular bundle is next tied, and the duodenum cleared to 2 inches beyond the pylorus and divided 1 inch beyond it. I crush and ligature the duodenum, burying the stump with a pursestring suture. The method is simple, very safe, and allows more distal division with proper invagination (Fig. 14).

The pyloric end of the stomach is held up, and the lesser omentum, a flimsy structure at this point, is cut with scissors down to the liver. The vascular lymphatic bundle of the left gastric artery is next defined. The lesser sac is seldom the clear space of anatomy books, and congenital fusions between the

peritoneum of the posterior gastric wall and that covering the pancreas are common. These are easily separated by scissors and blunt dissection, and the vascular bundle then stands out as a thick fold. The splenic artery can be seen leaving its base to run along the pancreas and the trunk of the left gastric can be felt in it as a taut cord when the stomach is pulled forward and to the left (Fig. 15).

The artery is cleared, where it leaves the celiac axis, and divided between 2 silk ligatures. With scissors the fatty and glandular tissue is then separated from the aorta and diaphragm up to the esophagus. There should be no bleeding. The stomach is next pulled strongly downward, and the glandular and fatty mass is stripped down from the cardia to a point 2 inches down the lesser curve. The peritoneum is divided with a knife, and the loose tissue pulled down with dissecting forceps. The entrant arteries and emergent veins are ligatured flush with the gastric wall. Finally, the left extremity of the great omentum is divided between ligatures, from the point to which it was separated from the transverse colon to one on the greater curvature just below the lower pole of the spleen.

A mass of tissue is thus prepared for removal that includes the growth, the stomach below a plane passing from the lesser curvature $1\frac{1}{2}$ inches from the cardia to the greater curvature just below the spleen, an inch of duodenum, the whole great omentum and superior surface of the transverse mesocolon, and all the lymph vessels and glands that accompany the left gastric and right gastropiploic arteries. The completion of the operation is a matter of technical preference rather than pathological principle. I prefer the valvular retrocolic gastrojejunal anastomosis first described by Lake, and I bring the duodenojejunal flexure above the mesocolon into the lesser sac, fix the highest part of the jejunum close to the diaphragm and close the mesocolic opening round the efferent jejunal loop only (Fig. 16).

This more radical dissection adds a little to the length and difficulty of the operation, but with local anesthesia the first is unimportant and the second moderate. It introduces fresh difficulties in the after care, for when the lymph

identified as discreet follicles but are diffusely scattered throughout the whole area and average in size about 1 millimeter in diameter. They are immediately below the superficial layer of the mucous membrane. In the fourth stage, these abscesses rupture and leave ulcers which appear as yellow spots scattered over the wall of the bowel, and which bleed on being wiped with a swab

The radiological evidences of the chronic stage are constant and marked by narrowing, shortening, hyperirritability, loss of haustration, and signs of destruction of the mucous membrane. Variations in the destruction of the mucous membrane are marked in the different stages of the disease and depend unquestionably upon the extent of bowel involvement, but the signs are too characteristic to be confused with other types of colitis. These laboratory evidences coupled with the clinical picture which is characteristic of thrombo-ulcerative colitis, assist in differentiating this type of colitis from other organic inflammatory lesions of the large bowel.

The clinical course of this chronic infectious disease of the colon is a characteristic one with an acute onset of many bloody stools likewise containing pus and mucus, the number of which sometimes ranges as high as 30 to 40 a day. Septic fever, anemia, and other evidences of infection exhaust and dehydrate the individual rapidly. This picture, along with sigmoidoscopic and roentgenographic evidence, easily and accurately establishes the diagnosis.

INDICATIONS FOR SURGERY

Medical management of chronic ulcerative colitis, which consists of a dietary regimen, administration of vitamin C, elimination of focal infections, and the use of vaccines and serum, is effectual in the majority of these cases to some degree. Intractability to medical treatment with a resulting damage of considerable extent to the colon, from which follows its loss of function and under which conditions the colon becomes filled with pus and detritus and is a source of absorption, is the principal indication for surgery.

Indeed, surgery for chronic ulcerative coli-

tis as for duodenal ulcer is indicated only for the complications which occur in 15 per cent of the cases. These complications, save only for hemorrhage and perforation, occur mostly in the chronic, intractable stages of the disease and fall readily into several classifications: (1) perforation, abscess formation, and hemorrhage usually occurring during the acute stages; (2) polyposis; (3) cancer developing on polyposis (this occurs in a definite percentage of cases, about 2.5 per cent); (4) visceral degenerative changes, (5) unique complications such as erythema nodosum, pyoderma gangrenosa, liver abscess, gastro-jejuno-colic fistula, etc., (6) evidences of focal infection, the lead-pipe colon filled with pus furnishing the source, as in arthritis, and (7) rectal complications such as stricture, fissure, peri-anal abscess, etc.

These complications, depending upon their distribution, the extension of the disease, and the acuteness or chronicity of the disease in each individual case, are indications for surgery of various types. The distribution is of particular importance because in 80 per cent of chronic ulcerative colitis cases as diagnosed by x-ray, the involvement of the large bowel is beyond the rectosigmoid juncture. In a series of 352 cases studied by Bargaen, Brown, and myself, roentgenography showed that the entire colon was invaded in 211 cases, 59.9 per cent, the lesion extended from the anus to the hepatic flexure in 240, 68.1 per cent, and from the anus to the splenic flexure in 69 cases, the rectum and sigmoid alone being involved in 26 cases.

This distribution is compatible with the data of other observers. Collins remarked that approximately 93 per cent of chronic ulcerative colitis is universal and only 7 per cent regional or segmental. In our experience, regional or segmental ulcerative colitis does occur, but very infrequently.

TYPES OF OPERATION

The operative procedures usually employed are. (1) colostomy; (2) ileostomy, (3) segmental resection by exteriorization; (4) subtotal colectomy following ileosigmoidostomy, and (5) subtotal or total colectomy following ileostomy.

SURGERY FOR ULCERATIVE COLITIS

FRED W. RANKIN, M.D., Sc.D., F.A.C.S., Lexington, Kentucky

THERE are few lesions of the gastrointestinal tract of a more controversial nature than so called chronic ulcerative colitis. Described first in 1875 by Wilks and Moxon, although a drawing by Cruveier some thirty to forty years previously accurately depicted the pathology of the lesion, it is a disease of the large bowel characterized pathologically by ulcerations, abscesses, and scars, and clinically by a syndrome associated with diarrhea, blood and pus in the stool, violent febrile reaction, prostration and weakness followed by periods of remission and with a proneness to multiple complications. Many names have been given to this ailment, varying from "idiopathic colitis" to the present day designation, "thrombo ulcerative colitis." Almost certainly we in America have been discussing a different pathological entity from the one our continental confreres commonly describe as chronic ulcerative colitis, and probably this explains in part the divergent opinions on the etiology, pathology, and particularly the treatment of this not uncommon disease.

ETIOLOGY

No phase of chronic ulcerative colitis is more debated than its etiology. Many organisms have been suggested as causative factors. Deficiency states as primary or secondary factors, are urged by some observers, and by and large there is scant unanimity of opinion regarding either the mechanism or the productive agents. That there are many types of ulcerative colitis, including tuberculous and amebic colitis, is general knowledge, but the pathological entity, usually referred to as chronic ulcerative colitis, is distinct from these.

The comprehensive, painstaking, and exhaustive work of Bargen, I feel, distinctly established the fact that a type of streptococcus produces 75 to 80 per cent of the cases of

ulcerative colitis. This type he terms, "thrombo ulcerative colitis" to designate its inception and pathology. The other 20 to 25 per cent of cases he points out, includes those in which there is an element of deficiency, some cases of allergy, a group of chronic bacillary dysentery cases, and that group in which the etiology is indeterminable. Bargen's researches which have been buttressed by application to clinical cases with undeniably advantageous end results in a large percentage of the group, have been, I believe, the most helpful factors in the modern management of this lamentable lesion.

DIAGNOSIS

The diagnosis of a typical case of thrombo ulcerative colitis depends chiefly on a combination of the evidences of pathology revealed by roentgenogram and sigmoidoscopy. The findings by sigmoidoscopy are variable but from the experience of many trained proctologists, a characteristic picture of the appearance of the bowel during the active stages and remissions of the disease has been outlined which is constant and trustworthy. Since the progression in the bowel is essentially from rectum to cecum in the vast majority of cases, and its tendency is to appear most characteristically in its active stages in the lower segment of the gastrointestinal tract easily available to proctoscopy, the early and late appearances of the lesion can be accurately established.

Buen's description of the mucous membrane of the bowel during the period of activity appears to me entirely adequate. He divides this period into four stages. The first is represented by a hyperemia usually most marked in the lower rectum and anal canal, and which fades into the normal mucosa above, the second is but an advancement of the first type and manifests itself as an edema and thickening of the mucous membrane which bleeds on slight trauma, the third is represented by milium abscesses in the mucosa which are not

tion of the colon in 6 cases, 3 of chronic ulcerative colitis and 3 of polyposis

The single-barrelled ileostomy which was utilized in that series may be criticized on one point, namely, that a stricture developing along the course of the colon in a blind loop of bowel filled with pus, prevents drainage. Recently I have modified this technique somewhat by bringing out both ends of the bowel, dividing it, leaving the clamp on the cecal end, and thrusting a pezzar catheter immediately into the proximal loop for drainage. The procedure is as follows: A split muscle incision is made at a point mid-way between the umbilicus and the anterior superior spine of the ilium on the right side. The ileum is picked up 12 to 14 centimeters from the ileocecal valve, the blood supply of this portion is ligated, and the bowel is severed between clamps, with a cautery. Instead of dropping the cecal end back as in the original technique, the clamp is left on the cecal end, a purse-string suture is placed around the ileal end, and a pezzar catheter is inserted. The two ends of the bowel are separated by the full thickness of the abdominal wall. The clamp is left on the cecal end for 48 hours or longer, but the immediate drainage of the ileostomy is advantageous.

The mobilization of the ileostomy from the abdominal wall in the second stage of the procedure is a little more difficult than when the cecal end is turned in and the bowel dropped back into the peritoneal cavity. Conditions in each individual case will determine which particular type of ileostomy is more desirable.

Ileostomy is always accompanied by great loss of body fluids and a concurrent decline in body weight. There is marked disturbance in mineral metabolism, loss of chlorides in the blood plasma, and a reduction of the serum calcium because of rapid and excessive loss of fluids. In addition, it is much more difficult to care for an ileostomy than a colostomy, but a satisfactory ileostomy bag which fits closely around the opening, keeping the discharge away from the skin has been adequate in our hands. The apparatus is made of non-metal and has a ring with a flange around it which fits a tight rubber dam through which a hole

Fig. 2. A long incision in the median line below the umbilicus and advancing upward splitting the muscle fibers of the left rectus muscle beyond that point as high as necessary, is the most useful incision. Regardless of whether a partial or total colectomy is to be done, the mobilization should be made from right to left and this incision allows handling of the entire colon most readily.

is made to fit the ileostomy so that the soft dental rubber sheeting of the dam is the only part touching the skin. Proper dietary habits will be of great assistance, and after a period of 3 to 4 months the ileum will assume in part the function of the colon, becoming larger and hypertrophied, and the patient will begin to gain weight and strength.

Colectomy. Before a colectomy, subtotal or total, is undertaken, pre-operative rehabilitation and decompression should be instituted with the most meticulous care. Adequate hydration by repeated small transfusions, intravenous administration of 5 per cent glucose in normal saline, plus a high caloric diet, are advantageous. Occasionally colonic irrigations may be of help, although frequently they are useless. Lead and opium pills 48 hours prior to operation are advantageous. These efforts increase the general resistance as well as supplement the advantageous effects of self-immunization, and thereby increase the margin of safety.

Removal of part of the colon by exteriorization or by a resection and immediate anastomosis has a limited field of usefulness. Actually, I question if either of these procedures is practical for chronic ulcerative colitis even

Fig 1 The split muscle incision has been made mid way between the anterior superior spine of the ilium and the umbilicus the ileum picked up 12 or 14 centimeters from the ileocecal valve the blood supply ligated and the ileum divided between clamps The clamp is left on the cecal end and a pezzar catheter put in the proximal loop for immediate drainage The two ends of the ileum are separated by the full thickness of the abdominal wall for about one half inch

Colostomy Colostomy is of relatively small use in most cases of chronic complicated ulcerative colitis. First, the disease generally involves the entire colon, second, if one makes a colostomy above the infected area in a regional ulcerative colitis, the disease has a tendency to leap over the colostomy and involve the segment above. How this is accomplished, whether by direct continuity of tissue, by the lymphatics, or through blood stream invasion, is not definitely established, but it has occurred not once but several times in my observation.

Jones, of Cleveland, has suggested that possibly a colostomy with complete division of the bowel and mesentery might be a useful operation for colitis situated in the left half of the colon. So far as I know, this procedure has not been tried out in any large series of cases and its utility remains to be proven.

Ileostomy Ileostomy has 2 indications: first, in chronic ulcerative colitis either as the first stage of a graded procedure for colectomy, or as a permanent drainage operation, and second, in the acute fulminating stage. In this latter condition, I question if ileostomy or any other operation is of much use, but if surgery is indicated for hemorrhagic, fulminating infection or the acute toxemia which goes with a violent case of ulcerative colitis, by passing of the fecal current by ileostomy is the method of choice. It should not be performed in uncomplicated cases and except in

a very small selected group of the acute variety. As an instance of how futile ileostomy is as an agent in the acute group, two hemorrhagic cases in my service serve as examples. In both cases ileostomy was helpless to stop the hemorrhage and a fatal outcome resulted. Again, I would urge that once an ileostomy has been established, its closure is distinctly questionable. I have closed one case which remained symptom free for 2 years when an exacerbation necessitated the performance of a second ileostomy. Twice I have closed ileostomies with exacerbations, resulting during the hospital period, with a fatal outcome in each case.

In 1932 with Bargin and Brown, I reviewed the histories of 82 patients upon whom ileostomy had been performed for acute fulminating ulcerative colitis and progressive complicated ulcerative colitis with evidences of absorption. Following operation in this group there was a hospital mortality in 26 cases, or 31.7 per cent. This immense mortality and the unsatisfactory end result of ileostomy, plus the more satisfactory results of a better managed medical regimen, influenced us to abandon it more and more each year except as one part of multiple stage procedures.

The technique of ileostomy which I have found useful, with certain modifications, was described in *SURGERY, GYNECOLOGY AND OBSTETRICS*, August, 1932. I utilized the original technique as a preliminary step to total abla-

tion of the colon in 6 cases, 3 of chronic ulcerative colitis and 3 of polyposis

The single-barrelled ileostomy which was utilized in that series may be criticized on one point, namely, that a stricture developing along the course of the colon in a blind loop of bowel filled with pus, prevents drainage. Recently I have modified this technique somewhat by bringing out both ends of the bowel, dividing it, leaving the clamp on the cecal end, and thrusting a pezzar catheter immediately into the proximal loop for drainage. The procedure is as follows: A split muscle incision is made at a point mid-way between the umbilicus and the anterior superior spine of the ilium on the right side. The ileum is picked up 12 to 14 centimeters from the ileocecal valve, the blood supply of this portion is ligated, and the bowel is severed between clamps, with a cautery. Instead of dropping the cecal end back as in the original technique, the clamp is left on the cecal end, a purse-string suture is placed around the ileal end, and a pezzar catheter is inserted. The two ends of the bowel are separated by the full thickness of the abdominal wall. The clamp is left on the cecal end for 48 hours or longer, but the immediate drainage of the ileostomy is advantageous.

The mobilization of the ileostomy from the abdominal wall in the second stage of the procedure is a little more difficult than when the cecal end is turned in and the bowel dropped back into the peritoneal cavity. Conditions in each individual case will determine which particular type of ileostomy is more desirable.

Ileostomy is always accompanied by great loss of body fluids and a concurrent decline in body weight. There is marked disturbance in mineral metabolism, loss of chlorides in the blood plasma, and a reduction of the serum calcium because of rapid and excessive loss of fluids. In addition, it is much more difficult to care for an ileostomy than a colostomy, but a satisfactory ileostomy bag which fits closely around the opening, keeping the discharge away from the skin has been adequate in our hands. The apparatus is made of non-metal and has a ring with a flange around it which fits a tight rubber dam through which a hole

Fig 2 A long incision in the median line below the umbilicus and advancing upward splitting the muscle fibers of the left rectus muscle beyond that point as high as necessary, is the most useful incision. Regardless of whether a partial or total colectomy is to be done, the mobilization should be made from right to left and this incision allows handling of the entire colon most readily.

is made to fit the ileostomy so that the soft dental rubber sheeting of the dam is the only part touching the skin. Proper dietary habits will be of great assistance, and after a period of 3 to 4 months the ileum will assume in part the function of the colon, becoming larger and hypertrophied, and the patient will begin to gain weight and strength.

Colectomy Before a colectomy, subtotal or total, is undertaken, pre-operative rehabilitation and decompression should be instituted with the most meticulous care. Adequate hydration by repeated small transfusions, intravenous administration of 5 per cent glucose in normal saline, plus a high caloric diet, are advantageous. Occasionally colonic irrigations may be of help, although frequently they are useless. Lead and opium pills 48 hours prior to operation are advantageous. These efforts increase the general resistance as well as supplement the advantageous effects of self-immunization, and thereby increase the margin of safety.

Removal of part of the colon by exteriorization or by a resection and immediate anastomosis has a limited field of usefulness. Actually, I question if either of these procedures is practical for chronic ulcerative colitis even

Fig. 3 To illustrate mobilization of the colon on the right side and preservation of the omentum. Ample peritoneum is deliberately saved to cover all raw surfaces. Widespread dissection is not essential as in dealing with malignancy.

of the segmental variety. On the other hand, subtotal colectomy with ileosigmoidostomy or ileocolostomy, where the disease is limited to the right side of the colon and transverse segment, is distinctly a satisfactory procedure in that small group of cases in which the pathological process is so isolated. Subtotal colectomy following ileosigmoidostomy, whereby the entire colon down to the recto sigmoid juncture, is sacrificed for definite indications, is a useful operation and is utilisable in that group of cases in which for one reason or another it is not practical to do a third stage and removal of the rectal stump.

This operation presents no great technical difficulty since there does not have to be a widespread removal of the mesentery, as for malignancy, and in addition it is not only more simple, but desirable to save the omentum another condition different from that dealt with in malignancy. The operation is usually carried out through a long left rectus

incision, the lower part of which is a midline one from the umbilicus to the symphysis. The upper margin of the incision is extended as high as is necessary to mobilize the splenic flexure. The mobilization is usually made from right to left and freeing the cecum is sometimes difficult because of the type of ileostomy which has been made. The John Young Brown type of ileostomy is a loop variety of operation and the cecal end of the ileum is opened on the abdominal wall. This has to be mobilized, inverted, and dropped back and the mobilization of the cecum continued from that point.

There are two difficulties which one must keep in mind throughout the whole procedure of mobilization and they are the likelihood of encountering chronic pericolic abscesses which rupture easily into the peritoneal cavity or, owing to the friability of the wall of the colon, may open into its lumen, and second, the friability of the mesentery which is shortened and thickened, and in consequence, hemorrhage by retraction of the vessels into this fat may become a problem. The mobilization is begun after the ileum is freed and by rotating the cecum mesially and dividing the peritoneal leaflet at its fusion with the parietal peritoneum. The blood vessels are clamped and divided as they appear and the dissection is carried upward toward the hepatic flexure in the same manner as though one were dealing with cancer, except for the sacrifice of the mesentery. The two main structures to be identified are the right ureter and the retroperitoneal portion of the duodenum. The vessels having been ligated and divided as they appear, it is best to peritonealize the raw surfaces after the dissection has progressed to the hepatic flexure, thus completing the right half of the operation entirely before proceeding to the transverse segment. By drawing the omentum upward, one is able to separate it easily from the transverse segment, ligate the blood vessels in this portion, peritonealize the raw surfaces, and move over to the splenic flexure with little or no difficulty. The latter is difficult to mobilize since the attachments are short and when they are supplemented by additional inflammatory bands, the difficulty is increased. The spleno-

colic ligament is divided, the vessels to the segment are clamped off easily, and the mobilization of the descending colon and sigmoid proceeds. The left parietal peritoneal leaflet is divided similarly, the colon is rotated mesially, the surgeon working toward the pelvis. When one has freed the sigmoid down close to the rectosigmoid juncture, preserving if possible the superior hemorrhoidal vessels, it is necessary to locate a point at which the bowel will be divided. If a long piece of sigmoid is left intraperitoneal, it will be necessary to complete the operation as a combined abdominoperineal resection. If, however, one divides the bowel close to the rectosigmoid juncture and makes a new pelvic floor, posterior removal can be done later with less risk.

In dividing the bowel at whatever level, experience has taught me that it should be grasped with a soft rubber, right angle clamp and cut off with a cautery rather than to utilize a crushing clamp which will cut through the bowel wall, leaving the severed end wide open and spreading contamination. I think it wiser merely to sew over the end of the bowel rather than to try to invert it, for inversion of this thickened, friable piece of intestine is usually impossible. The end is wrapped in iodiform gauze and this is brought out of the lower incision, after being wrapped in rubber tissue, as a drain.

The third stage of the operation is either a combined abdominoperineal removal of the rectum similar to that done for cancer, or a posterior resection by Mummery's technique, depending upon where the division has been made and where the blood supply has been ligated. After this stage there is an evident change in the ileostomy, its irritability, and not infrequently the tendency to diarrhea become noticeably improved. Frequently the stools are diminished in number and the function of the large bowel taken on more equably. For this reason it seems to me that subtotal colectomy which has been preceded by ileostomy, should uniformly be followed by removal of the rectum, unless contra-indicated.

MORTALITY FOLLOWING RESECTION

The hospital death rate following total or subtotal colectomy for definite indications in

Fig 4 Illustrating the completed operation of subtotal colectomy following ileostomy. The peritonealization is satisfactory and the rectal stump dropped down retroperitoneally after ligation of the inferior mesenteric vessels. This type of operation can be followed by posterior resection for removal of the rectal stump. If more sigmoidal stump is left, a combined abdominoperineal operation is necessary.

properly selected cases is consonant with the mortality in other types of surgery of the colon for major organic lesions. The main indications for colectomy are: (1) congenital adenomatosis, and (2) refractory or complicated ulcerative colitis. It is quite apparent on survey of the scant literature available that when resection for chronic ulcerative colitis is indicated, the mortality figures are quite satisfactory.

In my own series of 12 colectomies, 7 total and 5 subtotal, the operation was performed for chronic ulcerative colitis 5 times and for adenomatosis 7 times. There was 1 death in this series and it was in a case of adenomatosis; no mortality occurred in the ulcerative colitis group. Cave has recently reported 2 total and 4 subtotal colectomies for chronic

Fig 5 Illustrating resection of the rectal stump extraperitoneally after the method of Mummery

ulcerative colitis with no deaths, and Cattell in a personal communication informs me that he has done 16 total and 6 subtotal colectomies for ulcerative colitis with a single death. These are small groups, to be sure, upon which to reckon statistics, but no very large series of colectomies having been published, they indicate that this formidable procedure of ablation of part or all of the large bowel may be carried out under proper circumstances with a reasonable casualty list.

These cases give the appearance of being extremely bad risks because of dehydration, desiccation, and generally exhausted condition due to absorption. On the other hand, the long time during which self immunization has taken place is an advantage to them against infection, and adequate preliminary preparatory treatment consisting of repeated transfusions and daily administration of large amounts of 5 per cent glucose in saline, raises their physiological equilibrium to a level safe for extensive surgical maneuvers.

The loss of the colon for whatever reason is not attended with serious disturbances of

physiology and when the ileum has assumed in part the function of the large bowel, and the disturbances in blood chemistry and mineral metabolism, which are temporarily upset, have been balanced and weight and strength have improved, many of these individuals return to a useful status.

While it is clear that surgery is indicated only under rare circumstances in chronic ulcerative colitis, the indications are definite that the mortality is reasonable and cure by removal of the extensively diseased bowel is effected under these circumstances in which less radical measures are inadequate.

CONCLUSIONS

1. Surgery in ulcerative colitis is indicated only for complications. These complications occur, first, as rectal or perirectal lesions, or second, usually affect the entire colon from rectosigmoid to cecum. The removal of part or all of the large bowel for chronic ulcerative colitis is definitely desirable when the colon has lost its function and becomes a focus of absorption.

2. Surgery in the acute, fulminating or hemorrhagic forms of ulcerative colitis has few, if any, advantages. In this type of condition, ileostomy which completely by-passes the fecal current may be done under local anesthesia and occasionally appears to accomplish something.

3. Operations for colectomy, total or subtotal, should be carried out in multiple stages. Multiple stage operations increase the margin of safety enormously and sufficient time after performance of ileostomy should be allowed to elapse before resection is undertaken, to replace fluid loss, balance the blood chemistry, and increase body weight and strength.

4. Mortality statistics, following colectomy, parallel statistics for surgery of other major lesions of the colon.

5. The treatment of chronic ulcerative colitis is predominantly medical and no operation should be attempted until all other efforts have proved futile. But when surgery is undertaken, it should be only after adequate and prolonged pre-operative preparation and rehabilitation.

REGIONAL ILEITIS

BURRILL B. CROHN, M.D., New York, New York

IT IS just about 6 years since the publication of a paper (4) on the clinical and pathological description of a disease entity, styled regional or terminal ileitis. This is a chronic, non specific, granulomatous, inflammatory process occupying for the most part the terminal segment of the ileum, and characterized by diarrhea, fever, obstructive phenomena, and often by fistulous tracts, a disease which lends itself favorably to surgical operation. While making no stated claim to priority, we did feel that although non specific granulomas of the alimentary tract had previously been noted by several observers (17, 18, 25), the clear cut clinical picture, the roentgenographic appearance, the course and surgical treatment had never been intelligently portrayed, nor had the clinical condition received proper recognition.

Confirmation by current literature of the symptom complex followed within a few months (2, 11, 16) and still continues. Many of these authors confirmed in full the detailed features as we portrayed them, some have cast doubt on the disease as a clear cut entity. Intelligent criticism and supplementary observations of great interest and importance have received attention. On the whole, the subject has attracted the surgical fraternity into whose hands most of the cases either fall, or will fall eventually, and it is from them, with their biopsy *in vivo* that the most helpful ideas and the most pertinent suggestions have emanated.

To a large extent the original conception stands, nothing has been subtracted, but considerable has been added. It had been observed (1) that the disease might, on occasion, occupy other than just the terminal ileum, and that the upper ileum and even the jejunum might be affected independently of, or in conjunction with, the more consistently involved terminal segment of the ileum. The iron clad

rule of non involvement of the cecum and colon in true regional ileitis was soon broken down (3, 5), a fact to which we again acceded, adding the concept, exceptional though it be of a combined ileitis and colitis. New variations of the original fistulous tracts have been observed and confirmed.

The surgical approach to the solution of the problem has been a field of debate, the partisans of radical resection opposing the antagonistic upholders of short circuiting palliative measures. The suggestion has been made that the disease is a medical problem entirely and that surgery is superfluous.

Although the time elapsed is short, as time is measured in the world of science, nevertheless the opportunity is propitious for a restatement of views as judged from a broader concept and an ever increasing personal experience, with due acknowledgment of the opinions and statements of other competent observers.

This report is based upon 110 personally observed patients, 73 of whom have received confirmation by operation. Practically all of the remainder have been examined repeatedly and where feasible, an adequate follow up has been established and maintained. One hundred and ten cases seen in 6 to 8 years give an idea of the frequency and distribution of this singular disease. Its incidence is almost as great as that of ulcerative colitis, perhaps in the proportion of 1 case of ileitis to every 2 cases of colitis. Neither disease is rare. If alertness and the ability to recognize and interpret clinical symptoms be maintained, the cases will be encountered frequently in all classes of the population.

The point has been made in the literature that the disease appears to have its greatest incidence in the Hebrew race, if not exclusively so. This probably arises from the fact that the earlier confirmatory reports originated from the eastern seaboard, from such cities as Boston, New York, and Philadelphia, or from cities like San Francisco and Chicago with relatively large or proportionately large Jew

n populations. The rural districts to be heard from. My own experience in many of the published articles is purely racial distribution of the disease here or abroad. Sweden, South Holland, Canada, England, and Oklahoma instances of the disease in gentiles better acquaintance and a more wide recognition of the symptomatology, it questionable impression that the disease proved to have neither real racial predilection nor eventually, any preference for color. I have personally observed no case in the negro nor in the Porto Rican population of this cosmopolitan city.

The distribution of the sexes is not exactly even as is usually stated. There seems to be a definite preference for the male, the ratio being 66 males to 44 females, a proportion of 3 males to every 2 females.

The disease remains one of youth showing a definite predilection for the third and fourth decades of life. The youngest patient I have ever seen was 15 years old, the oldest, 58 years of age. The distribution of regional or terminal ileitis with regard to age, as I have found it, is as follows: first decade, none seen, second decade, 10 cases; third decade, 48 cases, fourth decade, 21 cases, fifth decade, 11 cases, sixth decade, 2 cases. More cases are noted between the ages of 20 and 30 years than in all the other decades combined. The average age of the illness, when seen, is 27.8 years. Many of the older patients have histories of such long duration that the origin of the diarrhea is easily dated in the previous decade or decades of life. Yet we must concede the fact that occasionally one does recognize a case *ab initio* in later years. A physician must be loathe, however, to diagnose ileitis in older persons without excluding the commoner diseases of middle life, particularly cancer.

Three times my opinion has been asked regarding the possible rôle of trauma in initiating ileitis or in aggravating present symptoms. On two occasions, automobile injuries, and on another, violent effort were impugned as causative agencies. In the 2 instances of automobile accidents, mild in themselves, no connection could logically be entertained be-

tween the slight trauma and a subsequent operation for chronic regional ileitis. In the third instance, hemorrhage into a pre-existing ileitis was claimed as the result of strenuous effort while engaged in an industrial pursuit. Here, some case for an exaggeration of pre-existing symptoms may possibly be made. To my mind it is unlikely trauma bears greater relationship to ileitis than to appendicitis.

CAUSATIVE AGENCIES

An actual etiological agency as the cause of ileitis has not been determined. We seem no nearer to the solving of this problem of the etiology of ileitis than we are to the similar puzzle of the creative factor in a case of ulcerative colitis. The latter disease has engaged close attention for many more years with extensive bacteriological research and animal experimentation without an acceptable solution. Both are regarded as non-specific diseases in which no single agent, bacterial or virus, can be successfully implicated.

The appendix has been accused by some (12), but its non-involvement in the pathological process in all but the most exceptional circumstances would seem to exclude it as an incriminating factor. In at least 33 per cent of our cases the appendix had been removed at a previous exploratory operation without affecting or inhibiting the course of the ileitis, nor did the appendix show any pathological changes characteristic of the disease.

Lymphatic block at the ileocecal junction with its maze of rich lymphatics has been accused of originating the disease (21), a type of lipin absorption from the lacteals being the provoking agent in a mononuclear cell type of infiltration. Experimental reproduction of lymphedema in this segment by injecting bismuth into the lymphatics has been adduced in support of this view. This hypothetical conjecture has no support in fact. The occasional recurrence of the disease process at higher levels of the ileum and the jejunum after previous resection of the terminal segments about the ileocecal angle speak loudly against a purely lymphatic block and in favor of a persisting residual infective agent.

I have seen the disease 3 times in siblings. The 2 earlier instances were reported in a pre-

Chart 1. Distribution of ileitis and jejunitis

viously published paper (6), the more recent instance is that of 2 brothers simultaneously affected by a rather acute process. This surely suggests a common infecting agent, probably bacterial, rather than a mere familial or tissue tendency to the disease. In none of these cases, nor in any other of the operative material, have I ever been able to recover a dysentery organism from either the stool or culture of the resected specimens. Moderately high agglutinations in the patients' serums have been observed occasionally, 1:320 Hiss was seen in 1 case. But the significance of agglutination reactions against dysentery organisms has been questioned recently as specific evidence for the existence of bacillary dysentery, unless supported by the actual recovery and growth of offending bacterias. The reaction is too general and too non-specific to be of any great significance.

The corroborative evidence offered by Felsen (9) to the incrimination of bacillary dysentery is not convincing but suggestive. The terminal ileum may be involved in severe, universal colitis caused by dysentery, as it is in the non-specific type, in 24 per cent, but the involvement of the ileum alone without participation of the colon is nowhere described in standard textbooks on pathology, nor will pathologists of repute accept such a conception. Felsen's epidemiological and clinical observations, regarding the persistence of ileitis

in a few survivors of a true epidemic of bacillary dysentery in Jersey City and elsewhere, is interesting but not convincing, because neither he nor others were able to recover a culture of the organisms in resected specimens.

The microscopic appearance of mononuclear cells in whorls with occasional giant cell inclusions suggest tubercle. The histological similarity to Boeck's sarcoid, as noted by Snapper (22), places both diseases as well as any other similar granulomatous process in the class of pseudotuberculosis. The disease is definitely not caused by the Koch bacillus.

PATHOLOGY

The pathological characteristics of the disease, as originally described, remain essentially identical with our original conception and require but few additional observations. The main brunt of the disease falls upon the terminal segments of the ileum beginning abruptly at the ileocecal valve and advancing upward along the intestine for a variable distance. The vast majority of the cases involve from 2 to 12 inches of the terminal segment of the ileum, but cases have been observed in which as many as 36 to 50 inches have been noted to be continuously affected. In 6 patients the whole of the lower and upper ileum was affected and in 2 at least the jejunum was probably similarly involved. In 1 case seen at autopsy, the small intestine including even the duodenum, was affected by a continuous inflammatory granulomatous process.

The extent of the involvement is usually announced by the presence of enlarged, succulent, mesenteric lymph nodes adjoining the mesenteric attachment of the intestine. These signal nodes appear paralleling the involved areas, and disappear when the unaffected or skipped-clear area is palpated. The nodes are never calcified nor do they often break down, they constitute an excellent guide to the exploring surgeon in determining the extent of the lesion. The presence of these guiding inflammatory nodes suggests the possibility that so called mesenteric lymphadenitis, as seen particularly in children, is none other than acute ileitis with minimal mucosal lesions and maximal lymphadenopathy. In the light of our increasing experience with ileitis, the concept

Chart 2. Skip areas in ileitis

of an independent disease such as mesenteric lymphadenitis, distinct and apart from ileitis, will bear more careful study. The transition of acute lymphadenitis to chronic ileitis has never been observed but is a reasonable potentiality.

Skip areas. The inflammatory process in the ileum is not always continuous, the pathological unity often being broken by one or more skip areas. These areas range from 2 to 12 inches, or as seen in 1 case, as many as 18 inches. They are of the greatest significance at the time of operation, for failure to note the higher skip areas means insufficient resection and accounts for the not inconsiderable percentage of recurrences.

Occasionally, though not often, it is found that the terminal ileum as well as some segments of the colon are similarly involved as observed in 8 cases. More often the cecum and ascending colon are affected in a continuous manner with the terminal ileum. At other times skip areas are seen in the colon, so that the process may appear, for example, in the terminal ileum, ascending colon, mid-transverse colon, or occasionally even in the sigmoid, with these various areas being separated by wide segments of unaffected mucosa. Fortunately for the original clear-cut description of regional ileitis, these combined cases of ileocolitis are few in number, for they represent very difficult problems in surgical judgment. When clinically observed over long periods of time, the colon involvement will often regress with only the diseased ileum remaining for resection. The converse, however, is often true.

Occasionally, the terminal ileum and colon are void of disease but the process is seen

involving a limited portion high in the ileum or even in the jejunum. These sections may be only a few inches wide in extent, or may involve more widespread areas with predominant lymphadenopathy. Resections at these points are more difficult and short-circuiting operations usually insufficient. While fistulization rarely takes place from sole involvement of these higher sectors of the jejunum and ileum, Dr A A Berg noted 1 such instance: a fistula originated in a diseased loop of the jejunum and ended in the sigmoid.

SYMPTOMATOLOGY

The onset of the disease is occasionally acute, as seen in 11 cases, but ordinarily the history is one of a chronic illness progressing insidiously. At first there are only occasional bouts of discomfort or diarrhea, later these are followed by continuous intestinal frequency, fever and pain. Sixty-two patients had a history dating from 1 to 5 years; 15 patients, 5 to 10 years; 8 patients, more than 15 years of almost uninterrupted illness. During this prolonged period of non-recognition, various diagnoses were maintained usually nervous diarrhea with a psychoneurotic background, at times food allergy, and undulant fever with peculiar intestinal changes was noted (24).

The appearance of the mass in the lower, right quadrant or across the lower abdomen is a later manifestation and betokens the spread of the disease into the mesentery, or the formation of sinuous, fistulous tracts may occur, and again there may be agglutination of variously affected coils of the involved small intestine. Not infrequently the mass represents a localized, low-grade, inflammatory peritonitis due to a walled-off slow per-

Chart 1 Distribution of ileitis and jejunitis

viously published paper (6), the more recent instance is that of 2 brothers simultaneously affected by a rather acute process. This surely suggests a common infecting agent, probably bacterial, rather than a mere familial or tissue tendency to the disease. of an independent disease such as mesenteric lymphadenitis, distinct and apart from ileitis, will bear more careful study. The transition of acute lymphadenitis to chronic ileitis has never been observed but is a reasonable potentiality

Skip areas The inflammatory process in the ileum is not always continuous, the pathological unity often being broken by one or more skip areas. These areas range from 2 to 12 inches, or as seen in 1 case, as many as 18 inches. They are of the greatest significance at the time of operation, for failure to note the higher skip areas means insufficient resection and accounts for the not inconsiderable percentage of recurrences.

Occasionally, though not often, it is found that the terminal ileum as well as some segments of the colon are similarly involved as observed in 8 cases. More often the cecum and ascending colon are affected in a continuous manner with the terminal ileum. At other times skip areas are seen in the colon, so that the process may appear, for example, in the terminal ileum, ascending colon, mid-transverse colon, or occasionally even in the sigmoid, with these various areas being separated by wide segments of unaffected mucosa. Fortunately for the original clear-cut description of regional ileitis, these combined cases of ileocolitis are few in number, for they represent very difficult problems in surgical judgment. When clinically observed over long periods of time, the colon involvement will often regress with only the diseased ileum remaining for resection. The converse, however, is often true.

Occasionally, the terminal ileum and colon are void of disease but the process is seen

involving a limited portion high in the ileum or even in the jejunum. These sections may be only a few inches wide in extent, or may involve more widespread areas with predominant lymphadenopathy. Resections at these points are more difficult and short-circuiting operations usually insufficient. While fistulization rarely takes place from sole involvement of these higher sectors of the jejunum and ileum, Dr. A. A. Berg noted 1 such instance, a fistula originated in a diseased loop of the jejunum and ended in the sigmoid.

SYMPTOMATOLOGY

The onset of the disease is occasionally acute, as seen in 11 cases, but ordinarily the history is one of a chronic illness progressing insidiously. At first there are only occasional bouts of discomfort or diarrhea; later these are followed by continuous intestinal frequency, fever and pain. Sixty-two patients had a history dating from 1 to 5 years; 15 patients, 5 to 10 years; 8 patients, more than 15 years of almost uninterrupted illness. During this prolonged period of non-recognition, various diagnoses were maintained: usually nervous diarrhea with a psychoneurotic background, at times food allergy, and undulant fever with peculiar intestinal changes was noted (24).

The appearance of the mass in the lower, right quadrant or across the lower abdomen is a later manifestation and betokens the spread of the disease into the mesentery; or the formation of sinuous, fistulous tracts may occur; and again there may be agglutination of variously affected coils of the involved small intestine. Not infrequently the mass represents a localized, low-grade, inflammatory peritonitis due to a walled-off slow per-

foration of the ileum, or to the breaking down of infected lymph nodes. The mass may resemble an appendiceal abscess, a urachal cyst, a diverticulitis with perforation, or possibly a secondary intestinal tuberculosis.

Obstructive symptoms do not appear as frequently as hitherto believed. In only 10 cases was intestinal obstruction a predominant phenomenon, which was always partial and incomplete and associated with borborygm, gurgling, and the palpation of the distended intestinal loops. An inflammatory mass with a long chronic history and signs of obstruction, when occurring in a young person, is highly suggestive of ileitis.

FISTULAS

The outstanding characteristic of this pathological process is its tendency to form fistulous tracts, it is by these tracts that the disease is known. These fistulous tracts are many and diverse, they travel wide distances and appear at unexpected exits. They seem to be chemical or lytic in action, and thus is created possibly by the solvent action of seeping intestinal juices containing activated digestive enzymes. They are seldom highly infectious and cause only a low grade, inflammatory abscess before perforating to the exterior. The following fistulas are recognized:

Internal fistulas, 11 cases. These originate in the terminal ileum but end in some segment of the colon, usually the cecum or the sigmoid. The ubiquitous and redundant sigmoid is frequently drawn up to the right, lower quadrant and attached to the inflammatory mass by an intercommunicating fistulous path, or the fistula may seek the transverse colon for its exit, or the rectum, the urinary bladder, vagina, or some contiguous and adherent loop of the ileum or the jejunum.

External fistulas, 12 cases. These fistulous tracts, again originating in a porous ileum, usually seek the anterior abdominal wall and follow the scar of a previous laparotomy. In fact, I recall no instance of an external fistula to the anterior abdominal wall except in cases in which a previous operation had predisposed the tissue to such a process.

Fistulous tracts to the inguinal, lateral abdominal walls and to the right lumbar regions

occur without antecedent operative measures and are apparently of a spontaneous nature. The most interesting are those in the lumbar gutter where they may be observed to form plural openings in a straight vertical line (237), emitting thin intestinal content.

Peri anal, rectal, and rectovaginal fistulas (8), 20 cases. These latter fistulas are the most common type of fistulization present in ileitis and deserve the most careful consideration. The methods of formation may be various. Most of the fistulas in ano occur as the result of infection in the rectal crypts of Morgagni by transported, contaminated, fecal material. This explanation probably answers for the large majority of simple peri anal fistulas.

But some of the fistulous tracts have a far more circuitous course. The diseased, heavy, and soggy terminal loop of the ileum lies usually on the pelvic floor near the pouch of Douglas, ascending at an acute angle to enter the ileocecal junction. Infectious pus and material escaping from the porous terminal loop of the ileum seep downward, infecting the pelvic peritoneum and retroperitoneal fat and burrow through the pelvic fascia by a fistulous tract which tends downward. This tract may make its exit into the rectum above the sphincters, or, piercing the sling like attachments of the levator ani to the sphincters, may exit at the peri anal margins. If the infectious fistula pierces the fibers of the levator ani laterally, the ischiorectal fossa is contaminated, and the abscess thus formed will make its exit as a pararectal fistula. In the female, the fistulous tracts may traverse the rectovaginal septum and make its exit in the perineum, the vagina, the rectum, or as a rectovaginal fistula!

The course of these long fistulous tracts is very difficult to follow. Lipiodol injections made from below are usually lost in a pool of radio-opaque material somewhere in the pelvis, the exact location of which defies analysis. On occasion we (8) have noted a streak of barium pointing sharply downward from the terminal ileum as seen during roentgenographic studies. At the same time or in the same case a lipiodol injection of a peri anal fistula will point sharply upward to the same

JHB

Fig 1. Diagram showing the course of fistulous tracts from diseased ileum to various points on the perineum

direction and location. While the direct path and continuity has not been unequivocally demonstrated, this explanation is offered as a reasonable and plausible analysis of the various chemical and anatomical factors involved.

The clinical significance of these peri-anal and rectal fistulas has not received sufficient recognition. They frequently precede anywhere from 1 to 14 years the onset of active diarrhea and abdominal pain, constituting the one prodromal symptom of regional ileitis.

In 1 instance a patient was admitted to the surgical services of the hospital for routine hemorrhoidectomy. A simple fistula-in-ano complicated the hemorrhoids. An alert interne, taking a routine history, discovered a story of mild diarrhea to which the patient himself had paid no attention. A gastrointestinal roentgenographic study exposed the presence of a terminal ileitis. Such an instance might be multiplied many times, if it were recognized by internists and surgeons that fistula-in-ano is so often a precursor of regional ileitis before the onset of active abdominal symptoms. Perhaps there is some pathological, bacteriological, or chemico-lytic affinity between fistula-in-ano and regional ileitis, since the same infectious process invades different but analogously susceptible regions of the intestinal tract.

Fig 2 Diagram showing the course of fistulous tract from diseased ileum via the ischio-rectal fossa to the perineum

COURSE AND PROGNOSIS

The acute cases of ileitis whether explored by operation or not, will, if not interfered with, run a variable course. Of the 11 patients seen with acute ileitis, many were explored but not otherwise resected; 3 have undergone a recession of their symptoms, suggesting that a spontaneous cure is possible occasionally. The experience of Koster (14) is similar to our own. He explored 6 patients with acute ileitis without further interference. They seem to have done well up to the time of the publication of his paper, though the duration of the follow-up is not specifically stated. However, considering the chronicity of the typical ileitis case, it is quite certain that the last word has not yet been said in these many instances (20). The 8 remaining patients did poorly; 6 of them were operated upon eventually.

The chronic case of ileitis that remains unoperated upon may come to grief. Two such cases came to autopsy. In both of them death was due to pelvic peritonitis with diffuse intra-abdominal suppuration and abscess formation. In the second case, a pelvic abscess perforated the urinary tract so that feces were passed through the urethra.

The usual chronic ileitis case runs a long course over a space of years. It is characterized by marasmus and nutritional disturbances due to protracted diarrhea and anemia, and ends eventually in the formation of multiple fistulas, or with the late picture of a

partial intestinal obstruction, when operative indications can be denied no longer. Spontaneous healing in a case of chronic regional ileitis has not been observed.

DIFFERENTIAL DIAGNOSIS

It can no longer be said that ileitis is a disease which defies accurate, pre-operative diagnosis. The clinical course is so typical, the negative sigmoidoscopy, and the barium enema which rules out the existence of a right-sided colitis, force one's attention to the small intestine as the most probable origin of the inflammatory diarrhea.

Roentgenographically, both the barium enema and the barium meal are highly efficient measures for the detection of the characteristic string sign (13, 10), or of an equally suggestive tuzziness and filling defect in the terminal or lower segments of the ileum. Very rarely will the roentgenogram fail. In 1 case only, a highly suggestive history led to the diagnosis of ileitis. A most competent radiologist declared the x-ray plates negative. Nevertheless laparotomy disclosed a typical but early terminal ileitis. This mistake in the interpretation of x-ray studies is so rare as to constitute the exception that proves the rule.

In the absence of the typical roentgenogram, other causes of diarrhea must be considered and ruled out such as thyrogenic diarrhea with its greatly heightened basal metabolism rate, the gastrogenic diarrhea of achylia gastrica or of a carcinoma anywhere in the stomach or in the alimentary tract. Diarrhea due to food allergy or purely nervous or emotional diarrhea require due consideration in evaluating intestinal hypermotility. Hence it is essential to get a complete personal history of each patient.

The greatest difficulty arises in differentiating cases of non tropical sprue from instances of high regional enteritis. The roentgenographic picture in sprue is not characteristic or constant and consists of puddling and delays in higher loops of the ileum and the jejunum without constant anatomical deformities. The stools of patients with sprue are characteristically frothy and abundant and do not, as in ileitis, show a constant positive test for occult blood. Anemia is most severe and often of a

hyperchromic type, the glossitis typical and the signs of an avitaminosis more likely to be present.

In enteritis, or high ileitis, the process usually is only an extension upward of a similar granuloma of the terminal ileum. The roentgenographic defect is structural and constant and the stools are more purulent and more often contain gross or occult blood.

If the physician be given a characteristic or a suggestive roentgenogram of an ileal defect knows the age of the patient and the protracted clinical course, there will be need for consideration of only very few differentiating conditions. Indigestion disease and multiple sarcomatosis of the small intestine are extremely rare in comparison with ileitis. Both of these diseases occupy by predilection higher sites in the small intestine than the terminal ileum. They both may give rise to profuse, gross hemorrhages in the intestinal tract a symptom which is unusual in ileitis.

In one case all differentiating signs failed. In a patient with a typical case history suggestive of all the classical signs of ileitis, except the fistulae, but with the characteristic roentgenogram, resection was done. The pathological examination surprisingly disclosed the terminal ileum occupied by a small infiltrating argentophilic carcinoid tumor.

In the past, most cases of ileitis were erroneously called primary intestinal tuberculosis. If such a condition exists as tuberculosis of the intestinal tract, independent of tuberculosis elsewhere as in the lungs, glands, pleura, joints, etc., then it is so rare that it fails to warrant the confusion it has originated. In a complete survey of all the postmortem and surgical, pathological material in Mt. Sinai Hospital, representing a vast accumulation over the last 15 years, only 4 cases of primary intestinal tuberculosis survived a critical analysis. In 2 of these patients the ileum was the site of a mucosal lesion with typical miliary tubercles and the tubercle bacilli were found in the intestinal lesions and nowhere else in the body. These 2 cases can not be denied and might have been confused with ileitis. All other cases of intestinal tuberculosis were traceable and were secondary to a primary focus elsewhere in the body.

TREATMENT

Regarding medical treatment, it can be said that apart from a non-roughage diet and general supportive measures nothing can be done to help the patient with ileitis. A direct therapeutic attack, in the absence of knowledge regarding the etiology, is impossible. In the cases of diffuse, almost universal involvement of the small intestine, one is forced to use medical means alone since the widespread anatomical distribution defies surgical measures. Surprisingly, these cases sometimes seem to improve under such simple measures, at least for the time being. Two such cases of diffuse ileojejunitis in which patients were not operated upon have been under observation for several years. One patient has gained as many as 50 pounds in weight under simple non-roughage diet and paregoric. The latest x-ray studies continue to show the lesion, but the general well-being of patient and inutility of surgery encourage further expectancy.

Surgery is the treatment of choice in all except acute cases of ileitis, and resection is probably the procedure which offers the best chance of permanent cure. I have no serious quarrel with any surgeon who prefers a short-circuiting operation to resection because of its lower risk, that is, 10.5 per cent, provided he understand that the patient has only an even chance of cure by this more conservative procedure. The notes of the 20 cases in which a short-circuiting operation had been performed, usually an ileocolostomy with transection and exclusion of the diseased ileum, disclosed the fact that exactly one-half or 10 patients are apparently well after a follow-up of 2 to 3 years. The 10 other patients did badly and had to submit to subsequent resection with a considerably higher, operative mortality. A primary resection can be undertaken with a moderate but not inconsiderable mortality, the rate being 15 per cent of 52 resections, but it offers the greater chance for permanent cure.

Unfortunately, one can no longer deny a certain percentage of recurrences even after what seems to have been a radical and sufficient resection (15, 19). The proportion at Mt Sinai Hospital has been 3 cases out of 39

operated upon, or 7.7 per cent. These recurrences can be explained only on 1 basis, namely, the inability of the surgeon to recognize the upper limit of mucosal involvement. Perhaps the enlarged mesenteric lymph nodes are not an infallible guide to the extent of the lesion; perhaps the advanced upper limit of infiltration is so minimal and so restricted to the mucosa as to create no hyperemic or inflammatory reaction in the serosa, thus defying detection by either inspection or palpation. We know that skip areas may leave as many as 12 to 18 inches of free uninvolved mucosa between minimal areas of diseased tissue. Recognition of these facts, and a most meticulous search of the entire ileum at the time of exploration may diminish or eliminate the chances of recurrence and lead to still greater improvement in an otherwise eminently satisfactory field of surgical endeavor.

REGIONAL ENTERITIS

CHARLES G MIXTER M.D., F.A.C.S., Boston, Massachusetts

FOR many years reports of benign non-specific intestinal granulomas have appeared in medical literature but no attempt had been made to classify these lesions until 1932 when Crohn, Ginzburg and Oppenheimer segregated from the general group of granulomas one having apparently definite clinical and pathological characteristics. Their experience was based on a series of 14 cases, in every instance of which the pathological process was sharply limited to the lower segment of the small bowel. In 13 of these cases a pathological study of the resected specimens showed a chronic inflammatory process with apparent limitation of the distal progress of the lesion by the ileocecal valve. On this basis they created a clinical and pathological entity which they termed regional ileitis.

The stimulus of this first communication is evidenced by the voluminous bibliography that has accumulated in the intervening 6 years. It soon became evident that the term regional ileitis was not sufficiently comprehensive, because of increasing reports of cases showing extension of the process to the colon and proximal small intestine either by contiguity or with intervening areas of apparently normal intestine. Even massive involvement, extending from the ileocecal valve to the ligament of Treitz has been encountered. For this reason the term, "regional ileitis," has been generally supplanted by the term, "regional enteritis," or "chronic cicatrizing enteritis."

The salient clinical and pathological features of the disease are as follows. It is a disease of youth. Fifty five per cent of our 20 cases were under 25 years of age and 18 were less than 35 (9). The cause is unknown. Primary infection of the appendix spreading to the ileum (4), bacillary dysentery (2), and a possible relationship to lymphogranuloma

inguinale (12) have been suggested. A superficial resemblance between mesenteric lymphadenitis and regional enteritis (5) has led to the supposition that both may possibly be due to a low grade primary infection of the lymphatic system. Although cultures from the lesion are usually either sterile or mixed, there are several reports in the literature of the isolation of a streptococcus (8, 10). In 2 of our less advanced cases an anaerobic streptococcus was obtained in pure culture from the free peritoneal fluid and from the cut surface of the mesenteric glands. However, we have been unable to reproduce the lesion in animals with this organism. Stagnation at the ileocecal valve and bacterial absorption through the rich lymphatic supply at the ileocecal angle have been considered accountable for the greater frequency of involvement of the terminal ileum (11). In no case has the tubercle bacillus been demonstrated.

The clinical features of regional enteritis are those of a low grade inflammatory lesion of the intestinal tract, often of months' or years' duration. The signs and symptoms depend on the location, extent, duration and severity of the process. The disease is progressive, though at times marked by remissions and exacerbations. Long latent periods may occur. Although spontaneous cure may take place, the definite establishment of this contention has yet to be confirmed by a long period of observation or by pathological demonstration in operatively proved cases.

The different stages of the disease are not sharply defined, but the 4 clinical phases described by Crohn and his co-workers have been generally accepted by subsequent observers. In the first phase the symptoms and signs are those of peritoneal irritation, namely, pain in the right lower quadrant, fever, leucocytosis, tenderness, and spasm. If this stage that has so often been erroneously diagnosed as acute appendicitis and in which operation has disclosed an edematous injected loop of terminal ileum with edema and hyper

plastic adenopathy of the mesentery and an excess of free peritoneal fluid. The appendix is not involved. Little opportunity for pathological study of this stage has been afforded as surgeons have felt that resection was not warranted in most instances.

The next step in the progress of the disease is the onset of symptoms suggestive of a mild ulcerative colitis: cramp-like abdominal pain, frequent loose bowel movements with mucus and rarely a small amount of blood, bouts of fever, weakness, and generally a marked loss of weight. There is low abdominal tenderness, and a mass may be palpated. Unlike colitis, tenesmus is absent and no ulcerations are disclosed on proctoscopic examination. Anemia and leucocytosis are commonly present. Perianal lesions, such as abscesses or fistulas, are not infrequently noted.

At this time the diseased segment appears thickened and edematous but less injected, and the serosal surface is granular and somewhat suggestive of miliary tuberculosis, though the nodules do not tend to bleed as readily. The mesentery is much thickened and the adenopathy is extreme. There is a tendency of the affected loop to agglutinate to surrounding structures.

On opening the resected specimen one is struck by the thickening of the intestinal wall, the definition of its layers due to edema especially of the submucosal layer. Numerous mucosal ulcerations appear particularly along the line of the mesenteric attachment. The lesion gradually shades off into normal bowel as it is followed orally from the ileocecal valve; but at times another area of disease may be found separated from the original lesion by an intervening segment of normal ileum.

The third stage is that of chronic partial intestinal obstruction. Severe colicky pain, distention, nausea and vomiting are present. Constipation may replace the previous diarrhea, but complete obstruction very rarely occurs. A mass is almost always palpable.

The diseased bowel is rigid and hose-like and the wall is tremendously thickened with consequent encroachment on the lumen. The mucosa has a cobble-stone appearance, the healing and contracture of the ulcerations

throwing intervening areas of uninvolved mucosa into prominence. An extreme degree of this condition produces polypoid masses that further obstruct the stenosed intestinal lumen. Above the stenotic area the lumen of the bowel is dilated but gradually diminishes with decreasing abnormality of its wall and lessening of the mesenteric edema. A complete return to normal intestine may be reached only several feet above the area of greatest activity.

There is a tendency to the formation of sinuses and fistulas in regional enteritis and such complications form the fourth phase. They are the result of slow perforation of the mucosal ulcers. Acute perforation is of extreme rarity and has occurred only in the upper small bowel in reported cases. One such instance appears in our series. Slow perforation of an ulcer at the mesenteric attachment may take place with the formation of a blind sinus or an abscess between the leaves of the mesentery or adjacent intestinal coils. As the diseased loop tends to adhere to adjacent structures, perforation of the ulcers may lead to internal fistulas, commonly to the cecum and ascending colon, then to the sigmoid, transverse colon, other loops of the small intestine, and occasionally to the bladder. Persistent draining sinuses, usually in the scar of a previous appendectomy incision, are not uncommon. At times numerous surgical attempts to close such sinuses have failed until resection of the underlying diseased bowel has been done.

Much stress has been laid on the value of roentgenographic examination in the diagnosis of regional enteritis. In the early development of the lesion no abnormality will be revealed but only the inconclusive evidence of hypermotility of the bowel, perhaps accompanied by cecal spasm. As the disease advances to the obstructive form, a definite filling defect in the ileum is observed with proximal stasis and dilatation. Increasing stenosis diminishes the bowel lumen until only a fine line of barium, the "string sign" of Kantor, is seen leading to the ileocecal valve. The string sign is not pathognomonic but is extremely suggestive of the diagnosis. In our experience intestinal films taken at hourly intervals furnish the most accurate data. The

barium enema will at times demonstrate a positive string sign and is helpful in defining internal fistulas and pressure defects on the colon from abscesses or agglutinated masses of the small bowel

No attempt will be made to discuss the differential diagnosis, but it should be emphasized that regional enteritis should always be considered when a young adult complains of symptoms of partial intestinal obstruction accompanied by the signs of a low grade inflammatory process. A somewhat prolonged history of colic like abdominal pain, irregular bowel habit, loss of weight, slight fever, and leucocytosis, is highly suggestive. Distention, a palpable mass on abdominal or rectal examination and the demonstration of the string sign on x ray investigation confirm the diagnosis

The time has been too short and the number of cases observed too few in any one clinic to permit the establishment of a fixed policy in the treatment of regional enteritis in its different stages. In the hope of obtaining information that would be of value in setting up a general technique of management, a questionnaire was sent to a limited number of clinics and surgeons in the United States. Thirty seven answers have been received and the data on 363 cases have been submitted for analysis from 31 individuals or clinics. The 6 other replies state that no instances of regional enteritis had been encountered. Only pathologically or operatively proved cases have been included in the series evaluated below. The follow up period has ranged from a few months to over 6 years, the majority having been observed for longer than 1 year. The largest single series was that of Crohn, 77 cases with operation in a total of 110 cases personally followed.

The adequate appraisal of the results of treatment be it medical or surgical, demands definite criteria by which the presence of persistent or recurrent disease may be determined. Obviously the return of persistent diarrhea, fever, and weight loss mean renewed activity of the lesion. However, many patients who have been restored to normal efficiency subsequent to radical surgical treatment, give evidence of some degree of hyper

motility of the bowel by x ray and by the passage of 2 or 3 semi formed or loose bowel movements a day. They have gained in weight and consider themselves well.

The presence of hypermotility is not in itself evidence of recurrence. Massive small intestinal resections for lesions other than regional enteritis may be followed by persistent hypermotility, for example.

A 38 year old man had an extensive small bowel resection for mesenteric venous thrombosis. Between 4 and 5 feet of gangrenous small bowel were removed. At the present time he is in good health attends to his profession as lawyer but passes an average of 3 loose stool daily. An x ray examination 18 months after operation showed marked hypermotility and moderate dilatation of the distal loops of the ileum.

From a detailed review of 257 cases of massive resection of the small bowel Haymond concluded that diarrhea was the most common and distressing postoperative disturbance. Consequently, a diagnosis of recurrence of regional enteritis should rest not only upon the evidence of hypermotility but also on the presence of bouts of fever, persistent diarrhea and loss of weight characteristic of the disease.

Of the 363 cases gathered by our questionnaire 278 have been subjected to major surgical procedures, and the total surgical mortality has been 1.5 per cent. Twenty five of the 27 surgeons who operated upon these patients consider radical resection in one or more stages as the treatment of choice in all but the earliest phase of the disease.

Although radical resection of the diseased bowel has been the most widely practiced surgical measure, the follow up studies show a very considerable percentage of recurrences. Koster, Kasman, and Sheinfeld reported 13 per cent of recurrences in 126 cases collected from the literature. Analysis of the material placed at our disposal shows a 20 per cent recurrence in the entire group in which operation was done. These recurrences appeared within periods varying from 4 months to 6 years. As one would surmise there is a far greater liability to recurrence in the advanced stages, so that it is clear that the optimum time for surgical intervention is in the earlier periods. Comparison of the statistics of medical and surgical treatment is manifestly

meaningless as patients presented for resection in most instances have progressed unfavorably under previous medical supervision. Furthermore, medically treated patients are not necessarily proved cases of the disease.

The treatment of regional enteritis can be best considered for each of its clinical stages. Surgical intervention in the acute stage is generally conceded to be unwise. Spontaneous resolution may occur. The danger of disseminating an acute infection by operative handling is possible. When the abdomen is opened under an erroneous diagnosis and an acute regional enteritis is encountered, incidental appendectomy should not be performed. Although in the past we have been guilty of this procedure in a few instances in our series at the Beth Israel Hospital, it is unsound to remove an appendix that is not implicated as a causative factor in the disease, in the presence of an acute infection. In addition, the risk of establishing an external fistula is great in a disease characterized by its tendency to fistula formation. The considerable number of patients presenting themselves with fistulas, frequently fecal in character and following a previous unnecessary appendectomy, is good evidence of this danger.

Accepting conservative measures as the preferable method of treatment in the acute stage, the progressive tendency of the disease must be kept constantly in mind. A strict medical regimen must be maintained with sufficient rest and a bland diet. If, after an adequate trial of from 3 to 6 months, the patient's condition continues to deteriorate, or should the signs of obstruction or other complications appear, a surgical approach should be considered.

There are no clearly defined boundaries between the clinical stages of regional enteritis; one phase merges gradually into another. Thus, early in the second or ulcerative stage where slight fibrotic changes have occurred, it is possible that complete regression to normal may spontaneously take place. But late in the same stage when infiltrating fibrosis has rendered the bowel rigid and inelastic and when encroachment on the lumen is already considerable though insufficient to produce

obstructive symptoms, it is hardly conceivable that restitution to normal can occur. If medical measures have failed to halt the progress of the lesion thus far, obstruction or fistula formation may be expected to follow. Surgical intervention should be employed before such developments take place.

In this stage the indications for radical resection are marked fibrotic changes in the intestinal wall and extensive mesenteric adenopathy. A wide excision of the diseased bowel and its mesentery, preferably in one stage, gives excellent results. We believe that the importance of an extensive excision of the involved mesentery should be emphasized, as it is possible that insufficient removal may be responsible for recurrence when the intestinal resection has appeared adequate. For this reason we consider resection and anastomosis preferable to a Mikulicz procedure in dealing with this condition.

The treatment of the advanced stages of the disease is unquestionably surgical. Graded procedures may be necessary. The patients are debilitated, and in the latest stages nutritional disturbances such as peripheral edema, neuritis, and anemia are often present. The common complications of abscess and fistula usually do not lend themselves safely to primary resection.

Obstruction, when present, is rarely complete and with appropriate pre-operative preparation a lateral anastomosis for its relief is usually permissible, though occasionally a preliminary ileostomy is indicated. The stoma should be placed well away from the upper limit of the lesion but an anastomosis in continuity should be avoided if possible. An unexpected delay in the performance of the resection may give the disease an opportunity to progress upward beyond the anastomosis and implicate the proximal intestine. As a curative measure the short circuiting procedures have never proved successful in our hands but apparently have been in the hands of others. However, the expression of opinion we have received is so strongly in favor of extirpation of the lesion that anastomosis must be considered merely a step toward the ultimate resection, when the patient's condition warrants the major procedure.

Fistulas commonly form between the terminal ileum and the cecum or ascending colon, and in this location can be readily dealt with at the time of the resection. When the fistula runs to the sigmoid it is not unusual to observe some evidence of the disease in the large bowel in this area. The wall is injected, somewhat thickened, and the serosa is granular. The sigmoid mesentery does not show the edema and adenopathy that is present in the mesentery of the ileum. Resection of the sigmoid is not necessary, and the lesion may be expected to subside following simple closure of the fistulous opening. Bladder fistulas, though of rare occurrence, may be similarly treated.

In a limited experience with the surgical treatment of multiple lesions involving the ileum and the sigmoid, the results have been far from satisfactory.

One patient following graded resections of both lesions showed gratifying improvement for 5 months. She then developed a fulminating recurrence with severe diarrhea. An end ileostomy was performed in a desperate attempt to afford relief. She died of peritonitis on the fourth postoperative day and at autopsy 4 perforations of the jejunum were found. There was massive involvement of the small bowel and of the colon to a lesser degree.

Lesions high in the small bowel appear to present the most virulent characteristics and it is in this situation that acute perforations into the free abdominal cavity occur. From our experience and that of others reported in the literature it would seem wise when possible, to avoid surgery in such cases.

SUMMARY

Much remains to be learned about regional enteritis. The etiology must be ascertained and the life history of the disease must be adequately traced. Unquestionably with advancing knowledge, our conception of the proper treatment will alter. At the present time it would appear that medical management is indicated in the acute stage of the disease. With continued progression in spite of an adequate period of intensive medical therapy radical surgical resection in one or more stages should be instituted. The outlook for restitution of health and prolonged arrest

or cure of the disease is good. Although it is impossible to state the actual number of cures in this series because of the wide variation in the period of follow up, it is evident from a study of the answers to our questionnaire that the operative mortality in the more complicated cases was much higher than in the simple or less complicated ones, and it is obvious that persistence in conservative therapy in these latter groups will work to the disadvantage of the patient.

The treatment of the advanced stages of the disease with obstructive abscess or fistula, is clearly surgical. Multiple stage procedures should be utilized, the final objective always being the resection of the involved bowel. The patient's condition is frequently precarious and a high mortality must be faced. It must be recognized also that the chance of recurrence is far greater than when dealing with the less advanced lesion. Nevertheless as the patient's progress is persistently downward and medical measures are futile, operation should be advised as offering the only opportunity for a return to health.

I wish to express my thanks for the co-operation and work required by the surgeons who kindly answered my questionnaire.

THE MEDICAL TREATMENT OF BRONCHIECTASIS

J. J. SINGER, M.D., Los Angeles, California

IN the study of pulmonary lesions it is absolutely necessary to have a correct diagnosis. Before the use of iodized oils, statistics on bronchiectasis were misleading because many cures which were reported by bronchoscopic drainage and various drugs and operations were due to spontaneous cures of lung abscesses, chronic pneumonitis or even fungus diseases of the lungs. A positive diagnosis can now be made by proper instillation of iodized oils into the bronchial tree. Then and then only, can we be sure as to whether bronchiectasis is present or not.

In the neglected cases of bronchiectasis one frequently finds that the evidence of metastatic abscess in the brain or kidney and even amyloidosis overshadows the underlying pathology. Obviously, treatment must be applied to the bronchiectatic condition as well as to the other organs. Unfortunately, when these severe complications are present little can be accomplished by any form of treatment.

In the bronchiectasis found developing in children after measles or whooping cough, occasionally the condition clears spontaneously, particularly if the lesion is not present too long. The foreign body lesions frequently heal when the foreign body is either coughed up or removed bronchoscopically.

Before specific medical treatments are described it seems advisable to discuss the various types of bronchiectasis, the etiological factors, and clinical features.

TYPES OF BRONCHIECTASIS

There are two main types of bronchiectasis, universal and telangiectatic. The universal type is a general form which is said to affect an entire bronchus, while the telangiectatic form is the conversion of the lung as a whole, or in part, into a mass of cysts lined with light epithelium. In the latter form cysts some-

times occupy the entire chest cavity, and it is difficult to differentiate the condition from a spontaneous pneumothorax.

In the acquired form of bronchiectasis the disease is usually secondary to infection following inhalation of a foreign body into the bronchial tree, or the condition may follow the pneumonias associated with the exanthematous diseases.

Tuberculosis is frequently a precursor of dilatations of the bronchi. This is usually due to the fibrosis resulting in stenosis of some of the bronchi followed by infection and secondary dilatations. The physical changes in the lung are due, however, more to mechanical causes than infection. Mediastinal swellings, compression of the lung by fluid or by tumors, may secondarily produce bronchiectasis of irregular shapes. Tumors within the bronchi frequently act like foreign bodies and produce similar dilatations of the bronchi beyond the obstruction.

David T. Smith suggests that bronchiectasis could be produced by lesions associated with fusospirochetal infection. He states that the elastic tissue of the finer bronchi is weakened and may even rupture by the action of an aerobic group of organisms.

The age of the patient, the duration of the disease, acute exacerbations of infection, the physical state of the patient, particularly the condition of the upper respiratory tract, and also the condition of the heart, kidneys, and so forth, are important factors to be considered in a discussion of treatment.

CLINICAL FEATURES

Nearly all cases of bronchiectasis are more or less associated with pulmonary abscess. The duration of the disease is usually of many years' standing in adults and one can frequently trace the origin in most cases to pulmonary diseases in childhood or even infancy.

The complaints are not typical. The secondary complications, such as bronchitis, abscess, or pleuritic involvement, are the

Presented before the Clinical Congress of the American College of Surgeons, October 17-21, 1938. A paper presenting the "Surgical Treatment of Bronchiectasis" was read by Norman S. Shenstone and has been published elsewhere.

Fig 1 A Aspiration method of injecting lipiodol. Note the straight cannula placed between the uvula and the tonsil. B The oil is shown filling the inner arytenoid fossa and dripping into the larynx when the patient takes a deep breath.

symptoms which call for attention. Cough is the most important and frequent complaint. It is usually severe and persistent during a great part of the day and night. The secretion brought up varies in amount from a few cubic centimeters to 800 or 1000 cubic centimeters. It may be foul or bloody. At times the expectoration is so foul that it is not only disgusting to the family but to the patient himself. Fever, sweats, and chills are frequently associated with the disease but only when secondary abscesses are present. It is not unusual for recurrent attacks of so called pneumonitis to develop which in time may be followed by metastatic abscess of the brain, kidney, and in late stages with amyloidosis. Many patients have hypertrophic osteoarthropathy (club nails) particularly if the condition is of long standing.

The physical findings are vague in the chest. At times râles are present in one or both lower lobes. The character of these varies with the amount of secretion. Dullness on percussion is rare but increased whisper signs over the affected area may be the diagnostic sign. If drainage is accomplished by position, the increased whisper sounds are particularly loud.

It is the roentgenographic study of the lungs which establishes the diagnosis positively, particularly when iodized oil is injected into the bronchial tree. This can be

done easily. The patient faces a good light and is told to open his mouth as widely as possible, his tongue is grasped with a piece of gauze and is pulled out as far as possible. Iodized oil, which has previously been warmed in a syringe, is slowly injected into the post pharynx through a straight cannula while the patient breathes deeply. The patient is instructed not to swallow or cough during the injection. Local anesthesia is seldom necessary although in nervous patients it is advisable to use 1 per cent procaine as a spray to the pharynx. The roentgenogram after injection shows the various types of dilatation.

TREATMENT

It is quite evident from the descriptions given that no definite or specific treatment can be used for such a complex condition of bronchiectasis. A cure can be effected only when the diseased portion of the lung or the entire lung, if it is unusually involved, is removed surgically.

Much can be done, however, to relieve the symptoms which at times are most distressing. It should be appreciated that the infection of the bronchiectatic areas sometimes becomes quiescent and the symptoms of cough and expectoration disappear. The patient, and sometimes the physician, may think the patient is well although in many such cases the introduction of the iodized oil into the bronchi will demonstrate the presence of the dilatation just as before the so called cure.

Among the medical treatments suggested for bronchiectasis are the following: rest, diet, climate, postural drainage, thirst cure, heliotherapy, intravenous therapy, direct intra bronchial application of drugs, irrigation of the lung (bronchial lavage), inhalation of vapors, vaccine therapy, bronchoscopy, artificial pneumothorax, abdominal belts and oleothorax. So many treatments are offered but none of them has really done much to cure the patient, but the symptoms have been much ameliorated.

Rest. As in most pulmonary diseases, rest is an essential part of the treatment. The healing factors of the body are best able to function when there is freedom from exercise and work. It has been shown by Pritchard

Fig 2 Roentgenogram of a patient with bilateral bronchiectasis. One can see some irregular densities in both bases and hilar regions (See Fig 3)

Fig 3 After lipiodol injection one notes the true condition of cylindrical and clubbing bronchiectasis of both lungs. Without the oil no definite conclusion could be had concerning the pathological condition of the lungs.

that when patients with bronchiectasis are put to bed they cough less, gain weight and are generally better. The rest need not be as strict as in tuberculosis. Even when strict and prolonged, rest alone will not cure bronchiectasis.

Diet Diet should be simple and sufficient to provide caloric requirements which are increased whenever there is fever. No specific restrictions are indicated. Care should be taken to provide an adequate protein and vitamin intake. Vitamins may play an important part but as yet nothing definite has been proved of value in this disease.

Climate Close study of accumulated experience suggests that climate alone never cured bronchiectasis. It is undoubtedly true, however, that temporary, and in some cases, long lasting improvement results from change in climate. Some patients have apparently benefited from the dry, sunny climates of Arizona and New Mexico; others from the mountains or the seashore. In resistant cases, the desirable effects of climate should be tried whenever economic conditions permit.

Postural drainage Of all the measures for symptomatic relief, postural drainage is the most effective. While the method is simple,

symptoms which call for attention. Cough is the most important and frequent complaint. It is usually severe and persistent during a great part of the day and night. The secretion brought up varies in amount from a few cubic centimeters to 800 or 1000 cubic centimeters. It may be foul or bloody. At times the expectoration is so foul that it is not only disgusting to the family but to the patient himself. Fever, sweats, and chills are frequently associated with the disease but only when secondary abscesses are present. It is not unusual for recurrent attacks of so called pneumonitis to develop which in time may be followed by metastatic abscess of the brain, kidney, and in late stages, with amyloidosis. Many patients have hypertrophic osteoarthropathy (club nails) particularly if the condition is of long standing.

The physical findings are vague in the chest. At times rales are present in one or both lower lobes. The character of these varies with the amount of secretion. Dullness on percussion is rare but increased whisper signs over the affected area may be the diagnostic sign. If drainage is accomplished by position the increased whisper sounds are particularly loud.

It is the roentgenographic study of the lungs which establishes the diagnosis positively, particularly when iodized oil is injected into the bronchial tree. This can be

done easily. The patient faces a good light and is told to open his mouth as widely as possible, his tongue is grasped with a piece of gauze and is pulled out as far as possible. Iodized oil, which has previously been warmed in a syringe, is slowly injected into the post pharynx through a straight cannula while the patient breathes deeply. The patient is instructed not to swallow or cough during the injection. Local anesthesia is seldom necessary although in nervous patients it is advisable to use 1 per cent procaine as a spray to the pharynx. The roentgenogram after injection shows the various types of dilatation.

TREATMENT

It is quite evident from the descriptions given that no definite or specific treatment can be used for such a complex condition of bronchiectasis. A cure can be affected only when the diseased portion of the lung or the entire lung, if it is unusually involved, is removed surgically.

Much can be done, however, to relieve the symptoms which at times are most distressing. It should be appreciated that the infection of the bronchiectatic areas sometimes becomes quiescent and the symptoms of cough and expectoration disappear. The patient, and sometimes the physician, may think the patient is well although in many such cases the introduction of the iodized oil into the bronchi will demonstrate the presence of the dilatation just as before the so called cure.

Among the medical treatments suggested for bronchiectasis are the following: rest, diet, climate, postural drainage, thirst cure, heliotherapy, intravenous therapy, direct intra bronchial application of drugs, irrigation of the lung (bronchial lavage), inhalation of vapors, vaccine therapy, bronchoscopy, artificial pneumothorax, abdominal belts, and oleothorax. So many treatments are offered but none of them has really done much to cure the patient, but the symptoms have been much ameliorated.

Rest. As in most pulmonary diseases, rest is an essential part of the treatment. The healing factors of the body are best able to function when there is freedom from exercise and work. It has been shown by Pritchard

Fig 6 Postural drainage bed (Singer) found useful for patients who are too ill for the drainage table, and for postoperative positioning. The various positions are obtained by turning appropriate levers.

that the iodine content does not separate from the oil except in the gastro-intestinal tract where it is slowly absorbed and the iodine is eliminated through the kidneys. There is nothing in the iodized oil which prohibits the growth of bacteria. In fact it has been shown that the oil on agar plates does not prevent the growth of adjoining colonies of *Bacillus coli*, *Staphylococcus aureus* and *Streptococcus hæmolyticus*.

Since the iodized oils are not bacteriostatic, little effect might be expected from the introduction of 20 cubic centimeters of oil every 2 weeks. The effect of the oil is due to its weight which permits it to cover the bronchial walls with a coating of oil. This may, in a measure, prevent irritation of the mucous membrane by retained pus and organisms. It tends also to liquefy and to dilute the secretions so that in coughing the discharge is more easily expectorated.

There are certain patients who have an idiosyncrasy for iodine or bromine in any form, and it is always advisable to find out whether such a condition exists before the introduction of these oils into the lung. In these patients even a small amount of the oil may produce coryza, increased cough, and feeling of malaise. The oil should not be injected more often than once a week and the amount should vary between 10 and 20 cubic centimeters. It should be warmed to body heat before its introduction and should be introduced with the least possible mechanical disturbance. If one does not obtain good and positive results within 3 or 4 weeks, it is not advisable to continue the treatment.

Bronchial irrigation (lavage) This method of treatment has been suggested as far back as 1914 by Yankauer. It was done through a bronchoscope or by a soft rubber Condé catheter. Stutt and Wooding, employing a hypertonic mixture of a saline solution, report 35 per cent symptomatic cures in a series of 250 cases. For the study of the value of bronchial irrigation, this method employed is worthwhile, but we have found, in our own experience, that postural drainage with an occasional bronchoscopic aspiration served the same purpose. With all the benefits derived from lavage, the bronchial dilations still persisted.

Inhalations of medicated air and volatile drugs. The inhalations are not recommended. Many physicians, however, particularly in Europe, have developed chambers containing medicated air and have recommended it to patients with bronchiectasis. It is hard to believe how any such inhalations can improve the state of the bronchial tubes.

Vaccine therapy The autogenous or stock vaccines made from various mixtures of bacteria, that are present in the respiratory tract, have been recommended. In our own experience this has been of very little benefit even symptomatically. There are, however, many men who have used this treatment, particularly the autogenous form of vaccine and it would be quite difficult to argue the value of such treatment with those who believe in it. But the author cannot recommend it at this time. It is possible, however, that the experimental studies may eventually bring forth a vaccine that may be of considerable benefit.

Fig 5 Postural drainage table (Singer) made of metal tubing with a pivot and brake arrangement at center of table top. It is not necessary to tip the patient more than 5 minutes 2 or 3 times a day

detailed directions must be given patients if the most benefit is to be obtained. By observation of their own case some patients find that considerable drainage is obtained in certain positions and they are able to relieve themselves of large quantities of purulent sputum with little difficulty. It is obvious to this type of patient that the recommendation of postural drainage tables or beds are not advisable. The simplest form of postural drainage is the use of a see saw arrangement whereby a long board is attached to a carpenter's horse and the patient inclines himself at the proper angle (Fig 5).

A postural drainage bed has also been devised by the author (Fig 6). In this bed the patient can be placed without any effort, in almost any incline for drainage. The apparatus is simple and the various positions can be obtained by moving certain levers.

Another simple means for obtaining postural drainage is by kneeling on a chair with the hands on the floor. The length of time for each drainage varies with the pulmonary conditions but usually should not be over 2 to 5 minutes at a time. If drainage is obtained easily, it should be done two or three times a day. This keeps the bronchi empty most of the time and permits many patients to go about their work and play without discomfort. Drainage before bedtime is particularly help-

ful. In many cases the benefit derived from postural drainage is dramatic and the patient frequently believes that he is cured. Improvement may be prolonged but the underlying condition is not corrected.

Of great importance is the correction of chronic upper respiratory conditions and unless these conditions are attended to, other treatment is not effective. At this point one might mention the importance of close cooperation between the otolaryngologists and the physician. The attempt on the part of the physician to treat bronchiectasis alone meets with failure if there is a lack of cooperation.

The acute exacerbation in bronchiectasis is due frequently to conditions arising in the upper respiratory tract, and any treatment directed toward this condition may prevent aggravation of a pathological state in the lung which is always present in bronchiectasis.

Heliotherapy. This method of treatment has been given considerable attention but so far no change in the pulmonary lesions has been noted other than the general effects obtained by sunlight.

Intravenous therapy—nearsphenamine. This drug is given in similar doses as in the treatment of syphilis and occasionally one sees a clearing up of symptoms, particularly in the amount of sputum which is reduced, and the fetid odor which may be present disappears. But the number of patients who have been much benefited so far are few. There are some who prefer to give nearsphenamine in minute doses frequently repeated, but observation of results leads to the conclusion that one cannot expect too much from this mode of treatment. When properly given there is no harm in the use of this drug, and it seems to be worthwhile when administered in addition to other treatments particularly postural drainage and rest. Other drugs have been tried with even less benefit.

Intrabronchial application of drugs. Lipiodol and other iodized and bromized oils have been recommended as a treatment for bronchiectasis. The method of introducing the oil has been described previously (4). It might be well to note that the oil is a combination of some oil with iodine, and that the mixture is a physical rather than a chemical one, and

the oil injected into the pleural cavity to test the reaction of each patient to the oil. Two hundred cubic centimeters of the oil is injected after one determines that the patient can tolerate the treatment. At the following treatment, which may be 5 or 6 days later, larger amounts can be used. It may take 6 or 7 treatments to fill the cavity but one should always leave some space for the serous exudate which usually forms. If there is fever or irritating cough, it is not advisable to continue the treatment.

Postural drainage must be used in addition to oleothorax and other hygienic measures coincident with the oil treatment.

SUMMARY AND CONCLUSIONS

Such pity was aroused by the hopeless outlook of many patients before bronchiectasis was made a major study, that physicians and surgeons were stimulated to find something of benefit to these patients.

Bronchiectasis is still a serious disease which baffles the profession. The manifold character of the pathological process and the wide range of symptoms make it impossible to discuss the disease generally. Each type demands appropriate discussion and treatment.

In the diagnosis of these types, infinite care must be exercised to arrive at definite conclusions. Fortunately our methods of roentgenographic examinations, our expert laboratory facilities, and our increased acumen in physical diagnosis have enabled us to sift out properly the bronchiectasis from the many pulmonary cases which formerly were usually classed as tuberculosis, abscess of the lung, or even malignancy. Probably the greatest strides thus far have been in finding suitable cases for surgical approach.

It has taken almost 20 years to have a fairly good idea of bronchiectasis, but now, with the increased interest, the next few years may even find a cure.

The careful study of the bacteriological flora has also contributed much to our knowledge of bronchiectasis. The suggestion of the use of neoparsphenamine has been based on these studies.

The detailed treatment of sinus infections along with other symptomatic treatments have also been helpful.

The use of postural drainage has kept many patients so well drained of their purulent secretions that complications have been kept down to the minimum.

The use of compression belts to give the abdominal muscles support and also to raise the diaphragm has been effective in reducing discomforts of coughing and also aiding in the expectoration.

Finally, the medical treatments, while not always effective, have improved the patient so frequently that he can stand surgical treatment.

Roentgen therapy This method of treatment has been suggested by several authorities. The logic of the treatment is that the fibrosis of the lung can be produced which may in time, by the shrinking of the lung, close the bronchi and prevent puddling of secretions within them. While the clinical reports seem encouraging, it does not seem probable that a great deal of permanent good can result. In fact, when one considers that bronchiectasis is often produced by fibrosis, an uncontrolled fibrosis produced by roentgenotherapy may be just as bad as if the fibrosis was due to inflammation. Further studies with dosage and proper material may show that there is some benefit in the use of the roentgenotherapy. It is by no means a closed book. Cases described by Berck seem to have shown some improvement clinically.

Use of the bronchoscope The use of the bronchoscope has received considerable attention. Its value for diagnosis or for drainage of the bronchial tubes is not disputed. One of the greatest benefits derived from the use of the bronchoscope is the ability of the operator to dilate some of the bronchi and to remove some of the granulation tissue when it is within the optical field.

Whether patients have been cured by its use is another matter. There are many bronchi which cannot be aspirated, either because there is a stenosis or because they are too far away from the main stem bronchus. Therefore, the secretions retained in these areas may become inspissated with the possibility of small abscess formations. The bronchial tree can be compared to a large sponge with the inflammatory conditions narrowing bronchi here and producing dilatations there. The affected lobe or lobes are in such a physical state that drainage cannot be established from all its openings. Therefore, drainage through the bronchoscope can at best be only partially effective. One cannot expect that aspiration of pus from the bronchial dilatations will lead to cure when the bronchial walls are thickened by inflammatory tissue. The symptoms, however, are frequently relieved enough to permit the patient to carry on his daily activities. In a comparison with postural drainage, the bronchoscope may

drain out dilatations more quickly but the treatment is not a pleasant one and certainly is expensive.

In the active attempt to treat bronchiectasis with a bronchoscope, some men have gone too far particularly in the frequency and the length of time the bronchoscopic drainage has been done. It is the opinion of the writer that if no positive benefits are derived within the first few months, surgical methods should be considered in patients who are otherwise found suitable.

Pneumothorax Treatment by means of artificial pneumothorax has been extensively advocated, however, since the use of iodized oil has become established, the enthusiasm for this treatment has diminished. It has been found that even when the lung is well collapsed the bronchial dilatations are still present after the collapse of the lung. One might wonder how compression of a diseased lung in which there is fibrosis, with thickened and dilated bronchi, can be effective in changing these factors. It appears that the explanation of the improvements following pneumothorax treatment is based on the fact that the lung as a whole is put at rest and that as a result natural recuperative processes may become more effective. Drainage from some of the bronchi may be better as a result of a change in the direction of the bronchi by the pneumothorax. Symptomatic relief is occasionally sudden and dramatic but in the majority of instances no permanent benefit has resulted. It is customary to inject 200 to 300 cubic centimeters at a time repeated as frequently as the air is absorbed and the lung re-expands. One should discontinue treatment after a few months if definite improvement fails to manifest itself.

Oleoathorax When there is improvement from pneumothorax or when there is difficulty in continuing the treatments, oleoathorax may be instituted. In a few instances improvement has resulted when this method has been used. The lung can be kept compressed for several years.

The oil injected consists of 95 per cent liquid paraffine or olive oil to which is added 5 per cent gomenol. The treatment should be started with only a few cubic centimeters of

patient, bleeding from such an ulcer, returned not in 6 weeks but in a year

Of 44 patients, whose symptoms returned after gastric resection, only 5 were previously operated upon by me, 3 with the Billroth I, and 2 with the Hofmeister-Finsterer technique. It is interesting to note that there were 12 patients who had been operated upon by Lorenz who always did a Billroth II, resecting only the antrum

Of 19 cases with a previous radical operation for gastrojejunal ulcer 10 had a Y-shaped anastomosis according to Roux and 4 an entero-anastomosis which favors the development of a gastrojejunal ulcer. Three patients, upon whom I had previously performed a Billroth I, later required a resection for a recurrent duodenal ulcer

Repeated gastric operations are technically difficult due often to the many adhesions present. They are, therefore, attended with a higher mortality than ordinary. Of 331 patients operated upon, 39 died, or 11.7 per cent. By subtracting those cases complicated by acute perforation, acute hemorrhage, or gastrocolic fistula, the mortality rate drops to 8.6 per cent, or 299 cases with 26 deaths. Excision or closure of a perforated ulcer, pyloroplasty, sleeve resection of the stomach, or gastro-enterostomy without gastrojejunal ulcer, do not present unusual difficulties at the time of re-operation. In only 2 of 83 resections did the patient die—a mortality of 2.7 per cent.

With the radical operation for gastrojejunal ulcer following a posterior gastro-enterostomy the mortality increased to 6.8 per cent, or 116 cases with 8 deaths. This increase is due partly to the procedure of Billroth I or Hab-

RESULTS OF REPEATED OPERATIONS UPON THE STOMACH ESPECIALLY FOR GASTROJEJUNAL ULCERS

PROFESSOR HANS FINSTERER Vienna Austria

MY experience is based upon 331 repeated stomach operations, 2,753 operations for the relief of benign gastric lesions of which 2,433 were resections. On only 39 occasions did I perform the previous operation. Table I indicates the primary operation.

Closure of a perforated ulcer is an emergency operation. An acute ulcer may heal after closure but a chronic ulcer almost never heals until it is resected. Gastro enterostomy rarely leads to permanent cure. Zuckschwerdt and Eck report cures in only 21.5 per cent with the development of a gastrojejunal ulcer in 51 per cent. Personally I have for the past 20 years resorted to gastro enterostomy only in those cases with severe pyloric stenosis in which resection of the perforated ulcer was impossible. To prevent the development of a gastrojejunal ulcer these patients are strongly urged to return in 3 months for a radical resection even though they be free from signs and symptoms.

Recently I found in a 38 year old patient who 4 months previously had had a gastro enterostomy performed in my hospital for a perforated duodenal ulcer with pyloric stenosis a large gastrojejunal ulcer about to perforate into the transverse colon. Complete recovery followed the radical resection. Two other patients who failed to report as requested finally had to be operated upon for a gastrocolic fistula despite the fact that one of them was completely symptom free after the first operation.

The commonest preceding operation performed was a gastro enterostomy. 190 cases. In 12 of these no ulcer could be demonstrated upon re operating, only chronic gastritis with a hypertrophic pyloric stenosis. It is somewhat questionable whether they ever had an ulcer. In 4 patients with normal or reduced gastric acidity the gastro enterostomy was closed and Finney's operation performed that is gastroduodenostomy with division of the

pylorus. Eight patients due to high acidity, required a resection of the pylorus and antrum according to Billroth I or Haberer.

In 23 cases the chronic ulcer still persisted, without, however, a gastrojejunal ulcer. Years ago when confronted with this type of case I resected the stomach with the duodenal ulcer 3 times, and 3 times resected the pylorus and antrum when extirpation of the ulcer was impossible, not disturbing the previous gastro enterostomy. Due to inadequate resection none of these were cured. So for the past 20 years I have been closing the gastro enterostomy and after resection of two thirds of the stomach do an end to side anastomosis between the jejunum and the remaining portion of the stomach according to the Hofmeister Finsterer technique. All of these patients have been permanently cured.

In 155 cases a gastrojejunal ulcer had formed though often the old ulcer had healed. The patients developed signs and symptoms of the new ulcer soon after the gastro enterostomy was performed. They had received medical treatment for long periods without relief one case for 27 years and another for 30 years with repeated hemorrhages.

In 8 cases of resection for exclusion of an inoperable duodenal ulcer a planned 2 stage resection was done, removing the diseased gall bladder and excluding part of the antrum with the pylorus at the second stage. This latter was comparatively easy because the penetrating ulcer had already healed with a stenotic scar. Of the 9 cases in which a gastrojejunal ulcer developed after resection for exclusion I had performed the first operation in 4 instances. The cause of the return in 3 of these was inadequate gastric resection. From 1919 to 1920, I resected only the antrum. The fourth patient because of complications with cholelithiasis was advised to return in 6 weeks for the second operation in order to prevent the formation of a gastrojejunal ulcer. The

*Mortality rate following radical operations for gastrojejunal ulcer after gastro-enterostomy is 8.1 per cent, after resection, 23.5 per cent.

and (3) death from toxemia due to occlusion of the end to end anastomosis of the jejunum. Therefore, the mortality is but 5.6 per cent, or 5 deaths in 88 cases when the radical operation for gastrojejunal ulcer after posterior gastroenterostomy is performed according to the Hofmeister Finsterer technique.

The radical operation for recurrent ulcer following gastric resection has a marked higher mortality. Seven patients with recurrent duodenal ulcer following a Billroth I, and 3 with gastritis following a Billroth II, all without a gastrojejunal ulcer, were cured by a more completely radical procedure. However, radical surgery for gastrojejunal ulcer following resection was attended with a mortality of 23.5 per cent or 8 deaths in 34 patients so treated.

Of these 8, 4 required a general anesthetic, 2 ether one 220 another 250 cubic centimeters and 2 nitrous oxide to supplement the local anesthesia. Two patients died of sepsis following an esophageal fistula and a left sided subphrenic abscess, 1 died of heart failure and 1 died with carcinoma of the pancreas diagnosed at the time of operation and confirmed at autopsy. One patient, in whom difficulty was encountered when the mesocolon was sutured to the anterior wall of the stomach, vomited so strenuously after operation that he had to be re-operated upon twice. This patient finally died of pneumonia. Of the 2 deaths due to peritonitis, 1 patient had even traction of the small bowel for 9 hours before discovery and repair. This 46 year old patient had a large ventral hernia following the 2 previous laparotomies, which could not be properly repaired at the time of the third operation. The second death from peritonitis was due to infection, not, however, due to failure of the suture line.

The significant difference in the mortality rate following radical operations for gastrojejunal ulcer after gastroenterostomy, 8.1 per cent, and after resection, 23.5 per cent, should I believe, determine the indications for the management of a recurrent ulcer. Although I never hesitate to advise operation for a gastrojejunal ulcer following a gastroenterostomy in those cases in which the ulcer recurs after resection I advise medical treatment first. If repeated courses of treatment fail despite its danger, new surgical interference is indicated.

The radical operation for a recurrent gastrojejunal ulcer is attended with a higher mortality rate not only because it is more difficult to perform but also because the patient due to previous operations and prolonged illness,

has often become a morphine addict. Of 14 such patients 3 died, a mortality of 21.4 per cent.

A 47 year old colleague of mine, who had had 3 operations, 2 gastroenterotomies and 1 resection for a gastrojejunal ulcer with a Y shaped anastomosis, required further surgery to relieve the unendurable pain of a large penetrating gastrojejunal ulcer. This patient a morphine addict insisted upon a general anesthetic and 300 cubic centimeters of ether were administered. However the local anesthesia reduced the amount that would otherwise have been necessary. Thirty six hours after operation the patient died of cardiac failure despite the establishment of normal intestinal peristalsis.

A 29 year old patient who also had had 3 previous operations, a gastroenterostomy and 2 resections with a Y anastomosis, required surgical relief for a large penetrating ulcer. This patient died from peritonitis that developed not from seepage through the line of suture but from infection that developed as a result of the poor asepsis maintained in that operating room. The third death was due to necrosis of the wall of the stomach for during the resection the left gastric and last branch of the gastro-epiploic arteries had to be ligated and the diaphragmatic arteries failed to provide an adequate blood supply.

A gastroduodenal fistula complicating a gastrojejunal ulcer has a grave prognosis, for the patient loses weight very rapidly and may die of inanition without surgical interference. However, if such a fistula is not opposite the opening of the gastroenterostomy but is distal to it the patient may live for many years because most of the intestinal contents will proceed through its normal course into the small bowel and not through the short circuit into the colon.

Six years ago I operated upon a 50 year old patient on whom the roentgenologist Dr. Freud 14 years previously had demonstrated the existence of a jejuno-colic fistula following a gastroenterostomy. Finally, after years of reasonable comfort this patient sought relief for severe pains and repeated hemorrhages. A 2 fingers width jejuno-colic fistula was found in the distal loop of the jejunum 5 centimeters distal to the gastroenterostomy where there was also a gastrojejunal ulcer. Following resection of the colon with side to side anastomosis and resection of the duodenum and two-thirds of the stomach with anastomosis according to the Hofmeister Finsterer technique the patient completely recovered.

Gosset reports a similar case. The patient had a jejuno-colic fistula of 5 years' standing

and finally developed a gastrojejuno-colic fistula through the perforation of a second gastrojejunal ulcer

To control inanition it is sufficient to divide the colon and anastomotic loop closing both openings. To cure the patient a radical operation must be performed later when his condition improves. If the patient's condition is satisfactory, the radical operation for jejunal ulcer can be performed immediately after separation and suture of the colon. Both methods have their disadvantages, namely, the excision of the edges of the fistula and the suturing of the same are possible only when the opening is not too large, and the new lines of suture are placed in infected tissue, which, covered with omentum, may form an abscess that can perforate into the free peritoneal cavity and cause death from peritonitis.

I had 2 deaths in 6 such cases of radical operation for gastrojejunal ulcer with suturing of the colon, one of which was really quite interesting.

A 43 year old innkeeper had a posterior gastro-enterostomy performed 5 years previous for an acute perforated duodenal ulcer. In a short time after the operation he developed periodic pains and finally a profuse diarrhea. X-ray examination confirmed the existence of a gastrocolic fistula, and at operation a 2-fingers' width colic fistula was found with the walls of the colon infiltrated. The colon was separated from the stomach, the opening closed with 4 lines of sutures and covered with omentum, then two-thirds of the stomach with the anastomotic loop were resected and the duodenum closed blindly. An end-to-end anastomosis of the jejunum, and distally to this an end-to-side anastomosis were done according to the Hofmeister-Finsterer technique. Finally a drain was placed under the liver. At first the patient established normal peristalsis despite continuous fever suggestive of pneumonia. Suddenly on the sixteenth day he developed terrific pains on the left side of his abdomen similar to those of a perforation. Upon reopening the abdomen 5 hours later an abscess was found near the colon repair, although the suture line was intact. The peritoneal cavity and the abscess were irrigated with normal salt solution and drained. The patient expired 3 days later from spreading peritonitis. In this case it was a mistake to repair the colon without resection, a mistake to cover it with omentum, and a mistake not to extra-peritonealize and not to drain. It was impossible to save the patient after the abscess ruptured.

Thirteen patients required a radical operation for gastrojejunal ulcer and a resection of

the colon. Seven of them had a 1-stage colon resection with side-to-side anastomosis and 3 of these died.

A 63 year old man, who had been sign and symptom-free for 17 years after a gastro-enterostomy, suddenly developed a profuse diarrhea lasting 3 weeks. During the radical operation, while mobilizing the short afferent loop, the gastrojejunal ulcer perforated, infecting the operative field. Peritonitis and death followed. In a second case the peritonitis developed not as a complication of the operation or from leakage from the suture line, but from the inadequate asepsis of an unsatisfactory operating room, which manifested itself in less serious cases. The third death could have been prevented for it was a mistake to perform a one-stage resection of a colon filled with feces.

A 43 year old man, with a gastric history of 20 years' standing, 2 severe hemorrhages, a gastro-enterostomy performed 10 years previously with recurrence of periodic pains within 2 years, profuse diarrhea for 2 months and a loss of weight of 30 kilograms, presented a gastrocolic fistula. At the operation, performed on May 2, 1935, under splanchnic anesthesia, a posterior gastro-enterostomy with a large gastrojejunal ulcer, a 3-fingers' width colic fistula with proximal stenosis of the colon were found, and the ascending and transverse colon was filled with feces. With a side-to-side anastomosis, 10 centimeters of the colon were resected. Resection of the duodenum and three-fourths of the stomach with the anastomotic loop, an end-to-end anastomosis in the jejunum, closure of the duodenum, and an anterior gastro-enterostomy with entero-anastomosis were performed because of the resection of the colon. The abdomen was then closed. On the first postoperative day the pulse was 84, on the second 88 and on the

and (3) death from toxemia due to occlusion of the end to end anastomosis of the jejunum. Therefore, the mortality is but 5.6 per cent, or 5 deaths in 88 cases when the radical operation for gastrojejunal ulcer after posterior gastroenterostomy is performed according to the Hofmeister Finsterer technique.

The radical operation for recurrent ulcer following gastric resection has a marked higher mortality. Seven patients with recurrent duodenal ulcer following a Billroth I, and 3 with gastritis following a Billroth II, all without a gastrojejunal ulcer, were cured by a more completely radical procedure. However, radical surgery for gastrojejunal ulcer following resection was attended with a mortality of 23.5 per cent or 8 deaths in 34 patients so treated.

Of these 84 required a general anesthetic, 2 ether one 220 another 250 cubic centimeters and 2 nitrous oxide to supplement the local anesthesia. Two patients died of sepsis following an esophageal fistula and a left sided subphrenic abscess. 1 died of heart failure and 1 died with carcinoma of the pancreas diagnosed at the time of operation and confirmed at autopsy. One patient in whom difficulty was encountered when the meocolon was sutured to the anterior wall of the stomach vomited so strenuously after operation that he had to be re-operated upon twice. This patient finally died of pneumonia. Of the 2 deaths due to peritonitis 1 patient had even traction of the small bowel for 9 hours before discovery and repair. This 46 year old patient had a large ventral hernia, following the 2 previous laparotomies which could not be properly repaired at the time of the third operation. The second death from peritonitis was due to infection not however due to failure of the suture line.

The significant difference in the mortality rate following radical operations for gastrojejunal ulcer after gastroenterostomy, 5.6 per cent and after resection, 23.5 per cent, should I believe, determine the indications for the management of a recurrent ulcer. Although I never hesitate to advise operation for a gastrojejunal ulcer following a gastroenterostomy in those cases in which the ulcer recurs after resection, I advise medical treatment first. If repeated courses of treatment fail, despite its danger new surgical interference is indicated.

The radical operation for a recurrent gastrojejunal ulcer is attended with a higher mortality rate not only because it is more difficult to perform, but also because the patient, due to previous operations and prolonged illness,

has often become a morphine addict. Of 14 such patients 3 died, a mortality of 21.4 per cent.

A 47 year old colleague of mine who had had 3 operations 2 gastroenterostomies and 1 resection for a gastrojejunal ulcer, with a Y shaped anastomosis required further surgery to relieve the unbearable pain of a large penetrating gastrojejunal ulcer. This patient a morphine addict insisted upon a general anesthetic and 300 cubic centimeters of ether were administered. However the local anesthesia reduced the amount that would otherwise have been necessary. Thirty six hours after operation the patient died of cardiac failure despite the establishment of normal intestinal peristalsis.

A 29 year old patient who also had had 3 previous operations a gastroenterostomy and 2 resections with a Y anastomosis required surgical relief for a large penetrating ulcer. This patient died from peritonitis that developed not from seepage through the line of suture but from infection that developed as a result of the poor asepsis maintained in that operating room. The third death was due to necrosis of the wall of the stomach for during the resection the left gastric and last branch of the gastroepiploic arteries had to be ligated and the diaphragmatic arteries failed to provide an adequate blood supply.

A gastrocolic fistula complicating a gastrojejunal ulcer has a grave prognosis, for the patient loses weight very rapidly and may die of inanition without surgical interference. However if such a fistula is not opposite the opening of the gastroenterostomy but is distal to it the patient may live for many years because most of the intestinal contents will proceed through its normal course into the small bowel and not through the short circuit into the colon.

Six years ago I operated upon a 50 year old patient on whom the roentgenologist Dr. Freud 14 years previously had demonstrated the existence of a jejuno-colic fistula following a gastroenterostomy. Finally after years of reasonable comfort this patient sought relief for severe pains and repeated hemorrhages. A 2 fingers width jejuno-colic fistula was found in the distal loop of the jejunum 5 centimeters distal to the gastroenterostomy where there was also a gastrojejunal ulcer. Following resection of the colon with side to side anastomosis resection of the anastomotic loop with end to side anastomosis and resection of the duodenum and two-thirds of the stomach with anastomosis according to the Hofmeister Finsterer technique the patient completely recovered.

Gosset reports a similar case. The patient had a jejuno-colic fistula of 5 years standing.

progressive anemia, 2,500,000 red blood cells, hemoglobin 30 per cent, pulse 120, soft, on January 31, 1930. There was a large stump of stomach left after a Billroth II, the small and large intestines were filled with blood, and a callous gastrojejunal ulcer was present at the site of the gastro-enterostomy opening. The stump of the stomach and the jejunal loop were resected. The jejunum was united with an end-to-end anastomosis, and an end-to-side anastomosis was performed with the small stomach stump. The abdomen was then closed. The immediate course was good. The pulse on the second day was 80 and there were no pains. In the evening pains developed in the right lower abdomen with a temperature of 39 degrees centigrade, pulse 128. On the third day the pain was localized over the appendix. Fair results were obtained by enema. Consent to operate was refused by the patient upon advice from the internist. On the fourth day the pains extended anteriorly, temperature rose to 39.5 degrees centigrade, pulse 120, and the patient consented to the operation. A lateral incision evacuated a putrid hemorrhagic exudate from the retroperitoneal space. The appendix, retrocecal and gangrenous, could not be removed without opening the peritoneum. Drainage was resorted to, and bacteriological examination revealed streptococci, which accounted for the serum. In due time a septic diarrhea appeared and persisted for 5 days when the patient died.

In a 27 year old man, operated upon during the war, was found an erosion of the middle colic artery, that had developed on the tenth day of the hemorrhage. Despite severe anemia, pulse 146 palpable only over the carotid, the patient had been given 0.2 grains of morphine in the medical ward. During the operation, which consisted of ligature of the middle colic artery, excision of the anastomotic loop with the ulcer, extraperitonealization of the colon for the 2 stage operation, he repeatedly stopped breathing, because of paralysis of the respiratory center from the severe anemia and the morphine. The pulse remained 146, palpable only over the carotid. At the conclusion of the operation, respiration again stopped for which artificial resuscitation was continued for 1½ hours at which time the heart stopped.

In a third and fourth case of radical operation patients died from peritonitis and pneumonia. It is questionable whether these 2 deaths could have been prevented by doing only a simple operation, namely, excision of the bleeding ulcer. A transfusion might have saved them but due to the circumstances a transfusion was impossible.

The acute perforation of a gastrojejunal ulcer is a rare but serious complication which can be cured only by operating promptly. I have observed only 2 such cases.

One of these was a 78 year old man upon whom 28 years previously a surgeon had performed a gastro-

enterostomy for a duodenal ulcer. Despite the constant diet observed, this man had periodic pain. Suddenly he developed a severe gastric hemorrhage followed by a perforation 12 hours later. Eight hours later, with diffuse peritonitis present, the abdomen was opened under local anesthesia and evipan. Due to its size, closure of the ulcer was impossible. Therefore, the gastro-enterostomy was discontinued, the stomach closed, the ulcer excised from the jejunal loop, and the jejunum reunited with end-to-side anastomosis. The old duodenal ulcer was healed so that normal anatomic relations were restored, and the peritoneal cavity was irrigated with normal salt solution. The immediate response was good with normal peristalsis established. However, on the 5th day the patient developed a cerebral hemorrhage from which he died 24 hours later.

The radical operation for gastrojejunal ulcer, and especially for gastrocolic fistula, is so serious, that one must give the type of anesthesia careful consideration. More than 15 years ago I pointed out in my monograph that the

TABLE IV.—ANESTHESIA IN UNCOMPLICATED CASES

	Number	Mortality	Per cent
General narcosis	19	8	42.1
Localesenteric and splanchnic	177	16	9.0
Total	196	24	12.2

reduction in the mortality rate of major abdominal surgery, performed under local anesthesia, justifies its serious consideration. Today, based upon more than 6,000 laparotomies performed under different types of local anesthesia, I can corroborate that statement. By precluding deep ether anesthesia, one can prevent those deaths that, commonly ascribed to operative shock, are really due to the after-effects of protracted anesthesia upon the parenchymatous organs. Because the normal resistance of peritoneum and lung, otherwise affected by general anesthesia, are not disturbed by local anesthesia, a marked reduction in the number of deaths due to peritonitis and pneumonia can be effected. This is shown so well by the radical operation for gastrojejunal ulcer.

In 19 cases the operation was started under general anesthesia solely, upon the insistent demand of the patient who was really otherwise physically fit. Immediately after induction, the general anesthetic was supported by local infiltration of the abdominal wall and

third because peristalsis failed to establish itself a Witzel fistula was made in the cecum to relieve pressure on the sutures in the colon. Through this the bowel emptied itself but infection developed in the abdominal wall and after a continuous high temperature for 7 weeks the patient expired due to chronic sepsis.

The 2 stage colon resection is indicated in those individuals in whom simple closure of the fistula is impossible due to its size and to surrounding infected areas. With such a procedure one can achieve fine results. The following case history is an example of this procedure.

A 61 year old man was sent to me from Yugoslavia with a gastric history of 14 years. He had had 3 severe hemorrhages, a gastro enterostomy 3 years previously followed by recurrence of periodic pain and since then 5 profuse hemorrhages, severe diarrhea for 3 weeks, and fecal vomiting for 2 weeks accompanied by rapid loss of more than 20 kilograms in weight. An x ray diagnosis showed a gastrocolic fistula. The patient was emaciated, weighing but 40 kilograms although he was 175 centimeters tall. He was severely anemic, 2,500,000 red blood cells, hemoglobin 40 per cent and pulse 120. The operation was performed September 25, 1936, with splanchnic anesthesia, 70 cubic centimeters of one fourth per cent novocain being used. Many adhesions were found. There was a posterior gastro enterostomy with an entero anastomosis where an ulcer tumor the size of a man's fist had broken through the transverse colon. The duodenal ulcer had healed. The duodenum, two thirds of the stomach with the anastomotic loop and the entero anastomosis were resected. The duodenum was closed, the jejunum united with an end to end anastomosis and distally to this an end to side anastomosis with the remaining part of the stomach was performed. The transverse colon was resected, the distal end being closed and the proximal end sewed into the lower end of the incision as an artificial anus. The postoperative course was smooth. The specimen (Fig. 1) showed a very large opening, 5 centimeters in diameter, in the transverse colon opposite a very small gastro enterostomy opening. The proximal jejunal loop was dilated and the proximal portion of the transverse colon was stenosed. Convalescence was rapid with recovery of loss of weight. Six weeks later after mobilizing the splenic and hepatic flexures the colon was united with side to side anastomosis. From this the patient recovered quickly, regaining all weight loss. On July 20, 1938 this patient was entirely well.

Of 6 patients with a 2 stage colon resection, 2 died.

A 39 year old man died on the fifth postoperative day from peritonitis but the autopsy showed no

leakage through the anastomosis. A 58 year old patient with recurrent gastrojejunal ulcer died on the eleventh postoperative day with broncho-pneumonia due to severe chronic bronchitis. The autopsy revealed no pathological change in the abdomen.

Gastrojejunocolon resection is attended with a high mortality. In 1931, Gosset had collected from the literature reports of 28 cases with 12 deaths, a mortality of 42.8 per cent. Since 1931, 1 case each was reported by Hoffmann, McLean, and Verebely, 1 of which recovered. My own records show the same high mortality, 13 cases with 5 deaths. Perhaps the results can be improved with the 2 stage resection of Wilkie in which, at the first stage only, the fistulous tract is completely excluded and the colon reunited. Through this the danger of inanition can be avoided. After the patient has recovered sufficiently, the stomach, loop of the jejunum, and the excluded part of the colon can be resected in the usual manner, so that the danger of peritonitis, due to the separation of the colon and its closure, can be avoided altogether.

Prognosis in acute profuse hemorrhage depends upon the time of the operation. Even in severe cases the results are good, provided that operative treatment can be started within 24 to 48 hours without first attempting medical therapy. All of 5 such patients operated upon were cured. In 1 of these only the bleeding ulcer was excised, and in 4 a radical operation was performed. In 1 of these patients, a 40 year old man, the middle colic artery was eroded in the base of the penetrating ulcer.

With delayed operations that were performed after the third to the tenth day, because the hemorrhages persisted despite medical treatment and repeated transfusions, the results were not good. Of 6 such cases, 4 patients died. However, the death of 1 of the latter was due neither to hemorrhage nor to operation but to sepsis from a gangrenous appendix.

A 44 year old man gave a history of a pyloric and gastric resection 19 years previously after which there was a prompt return of his pains. He had had repeated courses of medical therapy with periods of improvement. Four severe hemorrhages occurred which were accompanied by fainting spells. The last hemorrhage taking place 4 days previous to admission. Hemorrhage recurred despite special medical treatment. The patient was operated upon for a

These deaths were the results of the 5 cases: 3 were due to general anes-; to the use of the method of Billroth I, erer's modification; 1 was due to the placed fixation suture of the mesocolon was the result of leakage from the end-anastomosis of the jejunum, which ed because the afferent loop of the end-anastomosis was so short that it pulled antly on the proximally located end-to-nastomosis; and finally 1 case was due to pse of the bowel through the abdominal nd which broke down because of an inop-le ventral hernia and vomiting, which eas-ould have been avoided by a properly ap-d abdominal binder. The 4 deaths from itonitis due to infection from without also ld have been avoided had it been possible perform all the operations in one reliable stitution instead of in 9 different hospitals. o, the mortality rate of radical operations erformed under local anesthesia could be re-duced to 4 per cent without selecting cases, which is, after all, the mortality rate of pri-mary ulcer resection.

Of greatest importance are the permanent results achieved by repeated gastric operations. What procedure should be adopted to prevent a recurrence? Is it possible to cure these pa-tients permanently through repeated opera-tions, or are they to be classified as surgically incurable due to a marked disposition toward developing recurrent ulcers? The answer to these questions could be learned only by sub-sequent re-examination, or at least from re-ports submitted by the patient. In those cases, lacking a follow-up report, can be in-cluded some who failed to reply, because they were either disappointed with end-results, or had even submitted to further surgery by some one else. Therefore, every statistical report including more than 10 per cent of such

mesentery in order to block the field of operation and so to prevent the operative shock described by Crile in his well known book, *Surgical Shock and Shockless Operations through Anoci-As oculation*, and also to reduce the amount of ether and nitrous oxide required. Ordinarily, with such a procedure only 180 to 300 cubic centimeters of open ether were required. Of these 19 patients 8 died, a mortality of 42.1 per cent.

In 3 instances the cause of death was an infection peritonitis, and subphrenic abscess. In a fourth re opening the abdomen revealed an obstruction high in the small bowel due to an adhesion of the bowel with a hematoma that had developed after operation. A 36 year old man who had to have a radical operation for a gastroyejunal ulcer following resection presented many adhesions about the proximal jejunal loops which had to be separated. Three days later when the wound had to be reopened for continuous vomiting only fresh adhesions were found and no peritonitis. The patient expired 3 hours after operation. There was no autopsy.

In 3 cases death could be accounted for by the general anesthetic.

A 58 year old man who insisted upon a general anesthetic and who had 120 cubic centimeters of open ether and 200 cubic centimeters of closed ether died suddenly 1 hour after the conclusion of the operation. Autopsy showed a thrombosis in the right coronary artery. A 47 year old colleague who was given 300 cubic centimeters of open ether in addition to the local anesthetic died 36 hours after operation of cardiac failure despite the fact that normal peristalsis had already re established itself. A 52 year old man given 300 cubic centimeters of open ether to support local anesthesia for a radical operation showed typical postanesthetic gastroduodenal atony that is continuous vomiting yet normal bowel movements. Intervention on the fourth day showed the stomach stump and proximal jejunal loop 1½ meters to be greatly dilated and parietic with the remaining small bowel showing normal peristalsis without any adhesions.

I have observed this atony 5 times in 700 laparotomies performed under a general anesthetic probably due to a paralysis of an innervation center for the stomach and upper part of the jejunum, and yet have never encountered such atony in over 6,000 operations performed under local anesthesia.

Of 209 operations performed under local anesthesia, 155 required no general anesthetic whatsoever while 54 required slight support with open ether, 30 to 50 cubic centimeters,

and at no time exceeding 150 cubic centimeters during the entire procedure. Of these 29 died, or 14.1 per cent. By subtracting 32 cases complicated with acute profuse hemorrhage, acute perforation, and gastroduodenal fistula, the correct mortality rate for radical operation under local anesthesia is only 9 per cent or 177 cases with 16 deaths. None of these died within the first 5 days of so called operative shock, and only 1 died with pneumonia.

A 70 year old man presented the following history. A gastro enterostomy had been performed 30 years prior to admission but his periodic pains returned together with repeated hemorrhages. Two months before frequent vomiting occurred and he had suffered a loss of 30 kilograms in weight. The laparotomy under splanchnic anesthesia using one fourth per cent novocain revealed a duodenal ulcer penetrating into the pancreas, a large gastroyejunal ulcer penetrating into pancreas and mesocolon and about to perforate into the transverse colon. The duodenum was resected without excising the base of the ulcer and the duodenum was closed. The gastroenterostomy loop was separated from the base of the ulcer which measured 5 by 3 by 2 centimeters. Resection of two thirds of the stomach with the anastomotic loop was performed and an end-to-end anastomosis of the jejunum distally to which an end-to-side anastomosis according to the Hofmeister Finsterer technique was done. The base of the ulcers was drained. There were no postoperative abdominal complications however the patient died 1 week later with bilateral bronchopneumonia which developed because he was too feeble to raise the sputum accumulating from his severe chronic bronchitis.

Three deaths, caused by peritonitis from leakage through the line of sutures, high intestinal obstruction through occlusion of the end to end anastomosis of the jejunum and acute pancreatitis, can be accounted for by the technique employed, either Billroth I or Haberer's modification of it. Two patients died with a subphrenic abscess and a gastric fistula. Of 7 deaths due to peritonitis 3 could have been avoided. One was caused by prolapse of the bowels due to a large inoperable ventral hernia, another was due to perforation of the anterior wall of the stomach induced by the cutting through of a poorly placed fixation suture of the mesocolon slit and another was the consequence of necrosis in the posterior wall of the stomach. Four deaths resulted from peritonitis that developed as a result of

of the posterior gastro-enterostomy with the gastrojejunal ulcer was done and a new gastro-enterostomy created. At the third operation which I performed in November, 1923, at the Buffalo Sisters Hospital, 2 callous gastrojejunal ulcers, an old duodenal ulcer, and a marked dilated stomach were found. A follow-up report from Dr. Burke related that the patient was well until 1931 at which time the periodic pain had returned, and that in 1934 an acute perforation of a recurring gastrojejunal ulcer was closed. No further reports were available on this case.

A 39 year old man had 6 operations performed upon his stomach from 1930 to 1934 including 1 gastro-enterostomy and 2 resections by other surgeons. In February, 1934, a seventh operation was performed by myself for a recurrent gastrojejunal ulcer, i. e., a resection of the large stomach stump with the anastomotic loop, end-to-end anastomosis with the jejunum, and end-to-side anastomosis with the stomach. Because of kinking of the afferent loop an entero-anastomosis had to be added. Nevertheless, after this operation pain soon recurred despite repeated efforts with medical therapy. In April, 1935, I performed the eighth operation and found a large gastrojejunal ulcer penetrating to the mesocolon and transverse colon. My procedure in operating was the following: Resection of the anastomotic loop with entero-anastomosis and with so small a portion of the stomach as was technically necessary, end-to-end anastomosis of the jejunum, distally end-to-side anastomosis according to Hofmeister-Finsterer and cholecystectomy. The patient has remained completely recovered during the past 3½ years.

Two physicians, one 67 and one 68 years old, are dissatisfied with operative results. In the first case, pain was produced by a large ventral hernia of 14 years' duration, there were repeated attacks of chronic obstruction and symptoms of too small a stomach due to its slow emptying, which was a direct result of many adhesions. In the second case, the recurrence of the ulcer can be explained. The accompanying entero-anastomosis failed to neutralize the acid gastric content at the point of the gastro-enterostomy. Despite the fact that practically no further stomach resection was performed, the patient remained permanently cured.

Every entero-anastomosis favors the development of a gastrojejunal ulcer if the bile and duodenal content really pass through the entero-anastomosis. This is not always so, because neutralization of the gastric content at the point of the gastro-enterostomy is impossible. For this reason I include entero-anastomosis only when there is kinking of the afferent jejunal loop.

Roux's Y-shaped anastomosis led to poor permanent results. Of 21 patients only 7 were

cured, 1 improved, while 13 or 61.9 per cent, remained unimproved. In 6 of these 13, the diagnosis of recurrent gastrojejunal ulcer was established upon re-operation, and in 7 the diagnosis was indicated by the recurrence of periodic pains, hemorrhage, and x-ray findings. If the gastric secretions have not become neutral, which does not always follow after resection of half of the stomach, and which almost never follows resection of the antrum, the gastrojejunal ulcer will recur after a Y-shaped anastomosis; because that part of the anastomotic loop between the gastro-enterostomy and the entero-anastomosis is exposed to the acid contents of the stomach which are first neutralized by bile and duodenal secretions at the entero-anastomosis. Only if the gastric secretions are neutral through extensive resection of the stomach, can one achieve a permanent cure with a Y-shaped anastomosis.

This is well illustrated by 2 patients, brothers, 42 and 44 years of age, upon whom I operated 19 years ago for gastrojejunal ulcers that developed after gastro-enterostomy. At this time only half of the dilated stomach with the pylorus and the anastomotic loop were removed, and a Y-anastomosis performed. After 6 weeks, pain, hemorrhage, and heartburn returned. Despite repeated efforts with medical therapy in various institutions there was no improvement. The pain finally became so severe that 6 grains of morphine administered every 24 hours failed to control it. At the third operation performed upon the brothers in 1921, a large recurrent gastrojejunal ulcer was found penetrating into the pancreas and mesentery of the anastomotic loop, and extending down to the junction with the afferent loop. At that time so large a part of the stomach and also of the Y-shaped anastomosis was resected that only about one-fifth of the normal stomach remained. A new Y-shaped anastomosis was performed. These patients recovered quickly, gaining 15 and 20 kilograms in weight, and have remained free from all symptoms for the past 17 years. Moreover, they observe no diet restrictions and are fully able to work.

I no longer employ the Y-shaped anastomosis, which I favored 15 years ago because it was somewhat easier to perform. The results obtained by it are poor. Moreover, 14 years ago I openly criticized this procedure which until recently was still practised by some surgeons. Lahey also criticizes this operation as a result of his unsatisfactory experiences.

TABLE VI—END RESULTS OF RADICAL OPERATIONS PERFORMED 1912-1935

Type of operation	Cured			Improved			Unimproved

Y shaped anastomosis (Roux)	21	7	33.3	1	4	7	13	6	9

*The total cured and improved according to the Hofmeister Finsterer technique is 95.7 per cent

cases is of little value. Because I failed to obtain follow up reports in 6 of the 9 patients operated upon for gastrojejunal ulcer in the States, my statistics for "lost" cases has increased to 6.4 per cent.

Recurrence of a gastrojejunal ulcer after excision is inevitable due to failure to remove one or more of the causal factors. The separation of a gastro enterostomy with closure of the stomach and the jejunum, thereby effecting restoration of normal anatomical relations, should be the method of choice according to Allen and Judd for the management of a gastrojejunal ulcer. This I do only when no gastrojejunal ulcer is present and moreover no ulcer probably ever was present. When a gastrojejunal ulcer is present the simple degastro enterostomy will lead to recurrent duodenal ulcer. I performed a typical resection upon 5 patients for recurrent duodenal ulcer following a simple degastro enterostomy for gastrojejunal ulcer which had been performed by other surgeons.

To prevent the recurrence of a gastrojejunal ulcer Baum and later Haberer advised the completion of the radical operation with a Billroth I. It is true that this will positively prevent the return of a gastrojejunal ulcer, but not the recurrence of a duodenal ulcer, because the resection simply cannot be as extensive as with the Billroth II or its modifications. Otherwise the tension on the suture lines leads to leakage, peritonitis, and death. According to the experimental work of Smidt, the removal of half of the stomach in the Billroth I may be sufficient because the entrance of the gastric content into the duodenum provokes a prompt reflex stimulus from Brunner's glands, which inhibits the production of

hydrochloric acid in the fundus. This reflex cannot start with a Billroth II except that there may be a retrograde filling of the duodenum.

With the Billroth I, my experiences have been unsatisfactory. In my work with 8 cases 1 patient failed to reply, 4 were cured, and 3 developed a recurrence of the duodenal ulcer as demonstrated at postmortem in 1 and reoperation in 2 cases. These latter were cured by a new extensive resection with anastomosis according to the Hofmeister Finsterer technique. Horsley also reports 2 recurrences of duodenal ulcer after a Billroth I.

The end to side gastroduodenostomy, according to Haberer, leads to better permanent results, because the acid gastric content enters the duodenum opposite the papilla and is immediately neutralized. Of 24 cases, 7 patients failed to report and 17 are fully cured, 77.2 per cent, 3 patients were improved, 2 of whom had developed pulmonary tuberculosis and 1 cholecystitis, and 2 were unimproved, 9 per cent.

A 38 year old man was symptom free for 6 years following a radical operation in 1928. Since 1934 he has had periodic pains and once a black tarry stool. A 37 year old man was symptom free for 2 years after which he developed periodic pains heartburn and repeated small hemorrhages and in May 1935 he had a severe hemorrhage. X ray examination then showed a callous gastric ulcer.

The best permanent results could be attained through the extensive resection of the stomach in which at least two-thirds to three-fourths of the stomach are removed, and an end to side anastomosis performed according to the Hofmeister Finsterer technique. Of 96 patients 83 are permanently cured, or 91.6 per cent. These have no dietetic restrictions, have gained up to 30 kilograms in weight, and are fully able to work. Forty one cases were operated upon 10 to 20 years ago, so that one can really consider them permanently cured. Four patients are improved for they have no pain, they do have occasional periods of anemia and 1 patient also has pulmonary tuberculosis. Four patients remain unimproved, or 4.1 per cent.

A 28 year old man in 1920 had a gastro enterostomy for a perforated duodenal ulcer. In 1927 an excision

to re-operate, he found 12 patients with hyperacidity, 12 patients with normal acidity, and 2 patients with hypoacidity, but not 1 patient with anacidity

It is true that extensive resection has some disadvantages especially the complaints referable to a small stomach. In my experience this is present only in the early months, disappearing in more than 90 per cent of such patients with the gradual dilatation of the anastomotic loop. Nor is there much likelihood that either secondary or pernicious anemia will develop, although I have observed 2 of the latter. With modern liver therapy these can be controlled easily. When comparing the minor complaints with the dangers of a gastrojejunal ulcer, one cannot consider the former justifiable contra-indications against extensive resection. And until a more effective nonoperative treatment is found, extensive primary gastric resection is justified to avoid a gastrojejunal ulcer as much as possible.

CONCLUSIONS

A report of 331 repeated gastric operations with a mortality of 11.7 per cent is given. After those cases complicated by acute perforation, acute hemorrhage or gastrocolic fistula are subtracted, the mortality drops to 8.6 per cent.

The most frequently performed previous operation was gastro-enterostomy, 190 cases, after which either the old ulcer had not healed, or a gastrojejunal ulcer had formed. Therefore, I consider gastro-enterostomy an operation to be performed only in rare, exceptional instances.

The radical operation for a gastrojejunal ulcer, following posterior gastro-enterostomy, shows a lower mortality, 6.8 per cent, than when it follows resection, 23.5 per cent. Therefore, an operation is indicated at once by the return of complaints in a patient after gastro-enterostomy, and it is to be delayed, if the complaints return after resection until at least several attempts with medical therapy have been made. The mortality rate attending the radical operation for recurrent gastrojejunal ulcer is 21.4 per cent.

The radical operation for a gastrocolic fistula has a higher mortality rate even if the

colon is only separated and closed. The danger lies in the unreliability of the colon sutures, due to the surrounding inflamed area, 6 cases with 2 deaths. The high mortality of 5 deaths out of 13 cases for resection of the stomach and colon can be reduced by performing a 2 stage resection of the colon.

In a case of acute profuse hemorrhage from a gastrojejunal ulcer, the radical operation performed immediately is attended with good results. I had 5 such patients and all were cured. If performed late after unsuccessful medical treatment, it is attended with poor results, for of 6 such patients, 4 died. Therefore, early surgical intervention should be instituted promptly.

In acute perforation even the lesser operation, either closure or excision of the ulcer, produces poor results.

The mortality rate attending the radical operation for gastrojejunal ulcer depends also upon the type of anesthetic employed. The radical operation under general anesthetic, ether or nitrous oxide, was performed rarely and only in uncomplicated cases, when the patients were young and strong and insisted upon it. Radical operation for gastrojejunal ulcer showed a mortality rate of 42.1 per cent, or 19 cases with 8 deaths. Of these, 3 deaths were directly attributable to the anesthetic. With local anesthesia, splanchnic anesthesia, the mortality rate was 14.1 per cent, or 209 cases with 29 deaths, and by subtracting the 32 cases complicated by acute hemorrhage, perforation, or gastrocolic fistula, the correct mortality rate is 9 per cent. There was not a single death after operation due to so called operative shock and only 1 death due to pneumonia, despite the fact that 14 patients ranged from 60 to 78 years of age.

The best permanent results are achieved with the extensive two-thirds to three-fourths resection of the stomach and the preparation of the end-to-side anastomosis according to Hofmeister-Finsterer, even though there may have been several preceding operations. Of 96 cases 88 are permanently cured, or 91.6 per cent.

With the Billroth I the end-results are not as good, 4 cases cured, 3 cases unimproved. With terminolateral gastroduodenostomy of

Those patients, in whom gastrojejunal ulcer recurs after repeated operations upon the stomach are often considered "surgically incurable" I have again and again asserted that those patients, classified by Mandl as "surgically incurable" after repeated operations upon the stomach, have never really had a gastric resection. Upon a patient so classified by Mandl a fourth operation, which was a typical resection of two thirds of the stomach, actually resulted in a permanent cure. The cause of repeated recurrent ulcers is not an unusual disposition to develop ulcers which cannot be controlled surgically, but is the failure to do a sufficiently extensive resection of the stomach, as for example, resection of only the antrum, or a Y shaped anastomosis, or an entero anastomosis. This can be illustrated by the following case:

A 33 year old man had had 4 operations upon the stomach by 4 different surgeons (1) a posterior gastro enterostomy (2) closure of the posterior gastro enterostomy and the formation of an anterior gastro-enterostomy with an entero anastomosis (3) resection of the pylorus and antrum with the anastomotic loop and an end to side anastomosis, and (4) a Y shaped anastomosis because of a recurrence of the gastrojejunal ulcer with stenosis following which a gastrocolic fistula developed with a marked loss of 40 pounds in weight. At the fifth operation performed under splanchnic anesthesia with one fourth per cent novocain solution it was found that the former ulcer at the end to side anastomosis had healed and a new ulcer had formed at the Y shaped anastomosis which had perforated into the colon. In operating, the following procedure was followed: Resection of the transverse colon resection of the large stump of the stomach lesser curvature 10 centimeters and greater curvature 15 centimeters with both anastomosis and the old entero anastomosis a side to side anastomosis of the transverse colon an end-to-end anastomosis of the jejunum and distally to this an end to side anastomosis with the stomach according to Hofmeister Finster. Recovery without complaints followed with a marked gain in weight of 20 kilograms. However 4 years later this patient died with tuberculosis of the larynx and lung. The autopsy revealed no pathological lesion in the stomach.

My statistics show 8 instances wherein the patient had been operated upon 3 to 6 times without permanent success. Nevertheless, even these cases could be permanently cured by another more extensive gastric resection.

Balfour had 3 similar cases of repeated recurrent ulcer following resections, in whom the

last operation of terminolateral gastroduodenostomy was attended with a permanent cure.

For the patient it is surely better to prevent a gastrojejunal ulcer with its high attendant mortality. This can be achieved if the gastroenterostomy is employed only in rare exceptional cases, and if, with the resection of the ulcer, or with my method of resection for exclusion of a non removal duodenal ulcer, a very large part of the stomach is removed so that permanent gastric anacidity is established. The removal of the antrum, i.e. the distal third of the stomach, which is still called an extensive gastric resection by many surgeons is no guarantee of permanent cure. At least two thirds of the stomach, and in cases with a marked dilatation of the stomach in which only the antrum is dilated three fourths and more of the stomach must be removed so that finally there remains only the normal cardiac third of the stomach. The resection can be considered adequate only when it continues to the point on the lesser curvature where the left gastric artery from the celiac axis comes to the stomach, and on the greater curvature to a point which is a hand's breadth to the left of its midpoint, recognizable by the absence of the arcade. Since 1918 I have recommended the two thirds resection as a routine method, but in 1920 Haberer and Schmieden disagreed because they believed that this operation was too radical and that resection of the antrum was sufficient. In 1922, Hohlbaum called this procedure vandalism in the field of surgery. But experience has shown that my proposition, namely, that the most reliable permanent cure could be effected only by the extensive two thirds resection of the stomach was correct. With resection of the antrum, which I occasionally performed years ago there was recurrence in 4 out of 28 patients so operated upon, 2 gastrojejunal ulcers, and 2 recurrent duodenal ulcers, while with the two thirds gastric resection employed in the last 15 years with over 1,500 cases only 1 patient had to be re-operated upon for gastrojejunal ulcer. Recurrence follows upon failure to establish anacidity by sufficient extensive resection. In 28 patients with gastrojejunal ulcer after resection upon whom I Riedemann had

RECURRENT HYPERTHYROIDISM

A Report of 306 Cases Operated upon from 1928 to 1937

RICHARD B. CATTELL, M D, F.A.C.S., and EDWARD S. MORGAN, M D.,
Boston, Massachusetts

RECURRENT or persistence of the symptoms of hyperthyroidism following surgical treatment is sufficiently frequent to demand our attention. Subtotal thyroidectomy is recognized as the most effective means of relieving the symptoms of hyperthyroidism as 90 to 95 per cent of patients obtain satisfactory results. In the small group of unrelieved patients the largest number of unsatisfactory results are due to the recurrence of symptoms. In spite of the large number of reports in the literature dealing with the surgical treatment of hyperthyroidism, there have been relatively few which have concerned themselves primarily with the problem of recurrent and persistent hyperthyroidism. Lahey and Clute (11), Thompson, Morris and Thompson, Jackson, Pemberton, Else, Crile, and more recently Gillette and Scott have presented the incidence, means of prevention, and treatment. In a previous report from this clinic, Lahey and Clute (11) reported 48 cases up to 1926. It is the purpose of this study to present the factors responsible for the persistence or recurrence of symptoms following operation, outlining the management of these cases at the Lahey Clinic during a 10 year period from 1928 to 1937 inclusive. During this time 306 patients were operated upon for this condition and an additional small group were treated medically.

DIAGNOSIS

The diagnosis of recurrent and persistent hyperthyroidism presents the identical problem as does the disease in its original form, and for this reason it is unnecessary to discuss this aspect in detail. With their previous experience these patients are likely to recognize the fact that they have had a recurrence

From the Department of Surgery, The Lahey Clinic
Presented before the Clinical Congress of the American College
of Surgeons, New York, October 17-21, 1938

of their trouble. In the milder cases, nervousness, persistent tachycardia, and palpitation are common complaints. Weight loss in spite of adequate food intake and inability to carry out a normal activity, without exaggeration of symptoms, make one suspicious of a return of the hyperthyroidism. A return of the eye signs, particularly stare and exophthalmos, is present. It is important to realize that palpitation of the thyroid remnants is unreliable. The scar tissue resulting from the previous subtotal thyroidectomy makes it difficult to outline the lateral thyroid lobes. For this reason particular emphasis should be placed on the patient's story rather than on the examination of the gland. The diagnosis will usually be established by determining the basal metabolic rate.

PERSISTENT AND RECURRENT HYPERTHYROIDISM

Patients presenting symptoms of hyperthyroidism following thyroidectomy should properly be divided into the two groups of persistent and recurrent hyperthyroidism. We consider that patients have persistent hyperthyroidism who have not been fully relieved of their symptoms following operation and who do not have a return of the basal metabolism to normal within a 6 month period. If the patient has been relieved of symptoms for an interval of 6 months or more and then has a return, he is considered to have recurrent hyperthyroidism. The division of the cases into these two groups seems important since they present different problems.

Persistent hyperthyroidism is due to the failure to remove sufficient thyroid gland at the original operation. This should properly imply an inadequate procedure and may be due to a number of factors. Dr. Lahey (13) has repeatedly emphasized the necessity of obtaining adequate exposure of the gland

Haberer 17 cases were cured, 77.2 per cent, 3 improved, 2 unimproved, 9 per cent. In both of these methods a less extensive gastric resection was performed.

With Roux's Y shaped anastomosis permanent results are the poorest, 7 cases cured, 1 case improved, 13 cases unimproved, or 61.9 per cent. There also the two thirds resection of the stomach was inadequate, for a permanent cure is possible only if the gastric juices remain absolutely anacid.

The recurrence of a gastrojejunal ulcer after radical operation is not due to special ulcer disposition but to technical faults, too limited resection, Y shaped anastomosis, or entero-anastomosis. Therefore, by avoiding these errors in technique, permanent cure is possible even after repeated resections. The term, "surgically incurable ulcer," is not applicable to this type of case.

The number of gastrojejunal ulcers can be diminished if the gastro enterostomy is employed in only rare and exceptional cases, and if with the resection of the ulcer and with the resection for exclusion of unremovable duodenal ulcer, not just the antrum, the distal third of the stomach, but at least two thirds of the stomach and in those instances with marked dilatation even three fourths are removed, so that only the normal cardiac third remains. The disadvantages of extensive gas-

tric resection, too small a stomach and anemia, are of little consequence, since they are more easily controlled than a gastrojejunal ulcer following inadequate gastric resection.

We especially wish to express our appreciation to Dr. Burwig, Buffalo, New York, for his translation of this paper from German into English.

RECURRENT HYPERTHYROIDISM

A Report of 306 Cases Operated upon from 1928 to 1937

RICHARD B. CATTELL, M.D., F.A.C.S., and EDWARD S. MORGAN, M.D.,
Boston, Massachusetts

RECURRENCE or persistence of the symptoms of hyperthyroidism following surgical treatment is sufficiently frequent to demand our attention. Subtotal thyroidectomy is recognized as the most effective means of relieving the symptoms of hyperthyroidism as 90 to 95 per cent of patients obtain satisfactory results. In the small group of unrelieved patients the largest number of unsatisfactory results are due to the recurrence of symptoms. In spite of the large number of reports in the literature dealing with the surgical treatment of hyperthyroidism, there have been relatively few which have concerned themselves primarily with the problem of recurrent and persistent hyperthyroidism. Lahey and Clute (11), Thompson, Morris and Thompson, Jackson, Pemberton, Else, Crile, and more recently Gillette and Scott have presented the incidence, means of prevention, and treatment. In a previous report from this clinic, Lahey and Clute (11) reported 48 cases up to 1926. It is the purpose of this study to present the factors responsible for the persistence or recurrence of symptoms following operation, outlining the management of these cases at the Lahey Clinic during a 10 year period from 1928 to 1937 inclusive. During this time 306 patients were operated upon for this condition and an additional small group were treated medically.

DIAGNOSIS

The diagnosis of recurrent and persistent hyperthyroidism presents the identical problem as does the disease in its original form, and for this reason it is unnecessary to discuss this aspect in detail. With their previous experience these patients are likely to recognize the fact that they have had a recurrence

of their trouble. In the milder cases, nervousness, persistent tachycardia, and palpitation are common complaints. Weight loss in spite of adequate food intake and inability to carry out a normal activity, without exaggeration of symptoms, make one suspicious of a return of the hyperthyroidism. A return of the eye signs, particularly stare and exophthalmos, is present. It is important to realize that palpitation of the thyroid remnants is unreliable. The scar tissue resulting from the previous subtotal thyroidectomy makes it difficult to outline the lateral thyroid lobes. For this reason particular emphasis should be placed on the patient's story rather than on the examination of the gland. The diagnosis will usually be established by determining the basal metabolic rate.

PERSISTENT AND RECURRENT HYPERTHYROIDISM

Patients presenting symptoms of hyperthyroidism following thyroidectomy should properly be divided into the two groups of persistent and recurrent hyperthyroidism. We consider that patients have persistent hyperthyroidism who have not been fully relieved of their symptoms following operation and who do not have a return of the basal metabolism to normal within a 6 month period. If the patient has been relieved of symptoms for an interval of 6 months or more and then has a return, he is considered to have recurrent hyperthyroidism. The division of the cases into these two groups seems important since they present different problems.

Persistent hyperthyroidism is due to the failure to remove sufficient thyroid gland at the original operation. This should properly imply an inadequate procedure and may be due to a number of factors. Dr. Lahey (13) has repeatedly emphasized the necessity of obtaining adequate exposure of the gland

From the Department of Surgery, The Lahey Clinic.
Presented before the Clinical Congress of the American College
of Surgeons, New York, October 17-21, 1938.

and states that it is impossible to estimate the amount of thyroid tissue removed unless exposure is obtained. Failure to remove all of the superior pole or retrolaryngeal extension is a frequent cause. Failure to remove a pyramidal lobe may likewise result in a persistence of symptoms. A technique which leaves a portion of the isthmus over the trachea does not permit accurate appraisal of the amount of thyroid tissue left *in situ*. Too much thyroid tissue may be left in the usual lateral remnants because of the fear of injury to the recurrent nerve or parathyroid glands. In more recent years when adequate subtotal thyroidectomy has been carried out, persistent hyperthyroidism has been much less frequent. With present day methods we can be less concerned with this condition.

Recurrent hyperthyroidism may occur in spite of apparently adequate subtotal thyroidectomy and may appear at any time following operation. The cause of recurrence is unknown and must be due to the same factors responsible for the original disease. Pemberton called attention to the fact that all recurrences cannot be related to the amount of tissue removed. Thompson *et al.*, Jackson Gillette, Lahey and Clute (11) have all stated that fewer recurrences would occur if sufficient thyroid tissue was removed at the first operation. Because of the frequency of recurrent hyperthyroidism its prevention should be attempted. The most important point emphasized by all authors is adequate subtotal thyroidectomy.

Jackson and Else reported that postoperative administration of iodine will prevent many cases. For a number of years we gave our patients 10 minims of Lugol's solution daily for 3 months following operation. In a later series and at the present time the administration of iodine is discontinued at the time of the patient's discharge from the hospital. A comparison of the recurrent rates in these two groups showed that the administration of iodine did not lower the incidence of recurrence in our cases (7). Brenizer stated that recurrences could not be prevented by iodine. The careful regulation of the lives of patients following subtotal thyroidectomy for a period of months or even a year does, we

believe, lessen the number of patients having later symptoms. This regimen should require adequate periods of rest during this convalescent period, relief of mental and physical stress, absence from work for 6 weeks to 3 months, and the avoidance of stimulants such as alcohol, tobacco, coffee, and tea.

Although a number of authors have stated that the means mentioned have reduced recurrences, it has been impossible to ascertain which patients are likely to have a recurrence of their hyperthyroidism. Cattell and Perkin (3) have recently called attention to the use of the pre-operative blood iodine level as a means of determining the cases that may recur. In a study of a group of 256 patients with exophthalmic goiter they found that all of the recurrent cases occurred in those patients having a pre-operative normal or low blood iodine. In the group of patients observed approximately one fourth had a normal or low blood iodine, yet all cases had an elevated basal metabolic rate. Further more, Perkin and Lahey (15) showed that this occurred most frequently in patients who had had the disease for over 1 year. Cattell and Perkin (3) concluded that a more radical subtotal thyroidectomy should be done in a patient having a normal or low pre-operative blood iodine level. This has been the only means so far presented that may aid in the prediction of cases that may have a recurrence of symptoms. In our experience, recurrence of symptoms rarely follows subtotal thyroidectomy for nodular goiter with hyperthyroidism (adenomatous goiter with secondary hyperthyroidism). Patients with a discrete adenoma with associated hyperthyroidism may be relieved by removal of the adenoma unless the remainder of the gland is hyperplastic. We (4) have previously recommended that all of these patients be submitted to subtotal thyroidectomy in order to avoid recurrence since it is not always possible at the time of operation to determine whether hyperplasia is present in the remainder of the gland.

INCIDENCE OF RECURRENCE OR PERSISTENCE

During the 10 year period 1928 to 1937 inclusive, 4,956 patients with hyperthyroid

ism were operated upon at the Lahey Clinic. During this time, 306 patients were operated upon for recurrence or persistence of hyperthyroidism (Table I). It is difficult to determine a true incidence of recurrence or persistence unless all cases are carefully followed for a number of years after operation by clinical observation and by basal metabolism determinations. In a group of 190 cases reported by Thompson, Morris and Thompson from the Massachusetts General Hospital, 19.5 per cent had recurrence of symptoms. Jackson, in presenting 22 cases of persistent and 36 cases of recurrent hyperthyroidism, did not state the recurrence rate. Joyce found a recurrence rate of 5.7 per cent in his cases with hyperplastic goiter. Collier and Potter

recurrence of symptoms may occur at any time after operation up to 10 years or more, all figures for recurrence are probably inaccurate.

There were 265 females in our series, or 86 per cent, and 41 males or 14 per cent, giving a ratio of approximately 6 to 1. The average age for both sexes was 39.5 years. In our experience, recurrent hyperthyroidism is rare in children.

TREATMENT

Three methods of treatment are available for patients with recurrent hyperthyroidism: radiation, medical, and surgical. Many of the patients with the mild recurrence of symptoms can be satisfactorily controlled with Lugol's solution. They should be carefully followed to make certain that their weight is maintained and that they are able to carry on a reasonable activity. Either medical or roentgen therapy can be used in the mild cases when the thyroid remnants are small. Operation is advised for all patients with persistent hyperthyroidism who are not relieved by medical measures. It has been our policy to do a subtotal excision of thyroid remnants in all cases in which the remnants are demonstrated to be enlarged, when weight is not maintained, when the basal metabolic rate is elevated, and when incapacity is present. The pre-operative preparation is the same as for other patients with hyperthyroidism.

It must be admitted that the secondary operations on the thyroid gland are frequently difficult and unless unusual care is exercised, postoperative complications may occur (Table II). A wide and adequate exposure of the entire gland is even more necessary than in a primary operation if injury is to be avoided to the internal jugular vein, parathyroid glands, and recurrent nerve. The prethyroid muscles should be divided, although it may be impossible to remove the sternothyroid muscle from the gland remnant. The internal jugular vein is then identified, dissected free, and retracted in order to obtain a wide lateral exposure. It is our practice routinely to expose and identify the recurrent nerve and make a careful search for the inferior parathyroid gland. The pyramidal lobe is removed if

TABLE I—INCIDENCE OF PERSISTENT AND RECURRENT HYPERTHYROIDISM IN 4,956^{*} CASES OF EXOPHTHALMIC GOITER FROM 1928 TO 1937

	No	Per cent
Persistent hyperthyroidism	119	2.4
Recurrent hyperthyroidism	187	3.7
Total	306	

*165 patients had been operated upon previously at the Lahey Clinic.

reported 267 cases of exophthalmic goiter with a recurrence rate of 4.8 per cent. In our group of 306 patients, 187 were operated upon for recurrent hyperthyroidism and 119 for persistent hyperthyroidism. Of this number, 165 or 53 per cent, had their initial operation at this clinic. Of the total number of cases in which the original operation was done at the clinic, 1.76 per cent of patients showed further symptoms and were operated upon for this condition during the same 10 year period, yet this does not represent the true incidence of the condition. Perkin (16) studied 750 consecutive cases of exophthalmic goiter at the Lahey Clinic, followed for 2 years after operation, and demonstrated a recurrence rate of 5.2 per cent. The average duration of time between the initial and second operation for our cases of recurrent hyperthyroidism was 7 years and 11 months, while in the group of persistent hyperthyroidism, operation was delayed for 2 years and 4 months. Since it has been demonstrated that

present, as well as all thyroid tissue over the trachea. Small portions of thyroid tissue are left along each side of the trachea, preserving as much of the thyroid capsule as possible. In this way the parathyroids will be preserved even though they cannot be identified. A more radical removal of thyroid tissue is carried out in all recurrent cases, as compared to the removal in primary operations.

POSTOPERATIVE COMPLICATIONS

The operative mortality in the 306 patients operated upon for recurrent and persistent hyperthyroidism was 1.9 per cent (Table II). This should be compared with our total mortality in all patients operated upon for exophthalmic goiter of 0.67 per cent. Postoperative parathyroid tetany occurred in 2.9

TABLE II — INCIDENCE OF POSTOPERATIVE COMPLICATIONS FOLLOWING SUBTOTAL THYROIDECTOMY

	Primary operation (4056 cases) per cent	Second operation (306 cases) per cent
Recurrence	3.3	9.2
Hypothyroidism	4.0	6.2
Parathyroid tetany	0.19	2.9
Recurrent laryngeal nerve injury	0	14.7
Wound hemorrhage	0.5	2.6
Tracheotomy	0.1	2.6
Wound infections	1.0	1.6
Operative mortality	0.67	1.9

per cent of the series, as compared with 0.2 per cent in patients not having previous thyroid operation. This high incidence of parathyroid tetany is due to the difficulty of identification of the parathyroid glands during the secondary operation. As stated earlier in this paper we estimate the incidence of recurrent hyperthyroidism in our cases to be 3.3 per cent. After subtotal excision of thyroid remnants, 9.2 per cent of our patients still presented symptoms of hyperthyroidism. This strongly suggests some extrathyroid phase of the disease. The most common postoperative complication was recurrent laryngeal nerve injury. Either temporary or permanent injury to one nerve was noted in 14.7 per cent. This high incidence of recurrent nerve injury has been one of the factors responsible for Dr. Lahey's (12) recom-

mendation that the recurrent nerve be visualized routinely in thyroid operations. If this be done, we know that this figure will be greatly lowered. Six and two tenths per cent of our patients showed postoperative hypothyroidism. This figure is not greatly in excess of the 4 per cent incidence in primary cases. Postoperative hemorrhage and wound infection occurred in a somewhat higher proportion than in primary operations. We wish to emphasize particularly the high occurrence of postoperative complications following subtotal excision of the thyroid remnants for it further emphasizes the seriousness of recurrent hyperthyroidism.

SUMMARY AND CONCLUSIONS

Persistent hyperthyroidism follows inadequate subtotal thyroidectomy and should be treated by subtotal excision of thyroid remnants.

A series of 306 patients operated upon for persistent or recurrent hyperthyroidism during a 10 year period is presented.

Radical subtotal thyroidectomy is recommended for all patients having a preoperative normal or low blood iodine.

Subtotal excision of thyroid remnants is a difficult operation and may be followed by a high incidence of postoperative complications. Means of reducing complications are discussed.

Patients having recurrent hyperthyroidism resulting in inability to maintain weight, with an increased metabolic rate, and inability to work, should be treated surgically.

CONTRACTURES DUE TO BURNS

W T COUGHLIN, M D, F A C S, St Louis Missouri

A CONTRACTURE is an abnormal shortening of the soft tissues whereby skeletal structures, and often the adjacent soft parts as well, are drawn into and fixed in abnormal position, so that the form is disfigured and the function interfered with. It has long been known that scar tissue contracts as it gets older, and all have noticed that those wounds which healed the most rapidly left the least scar.

Burns take longer to heal than wounds due to mechanical trauma, and almost all those of the third degree suppurate. The pyogenic process is an additional source of irritation to the already injured tissues and a greater production of new connective tissue occurs. Also, these injured tissues require a longer time to heal because not only have surface cells been immediately destroyed, but those directly below have been so seriously injured that they soon die, while those remaining viable are injured in decreasing degree of severity from the surface to the depths where normal tissues remain. Such injured cells cannot respond to the injury until they recover their vitality.

But it is not alone the amount of connective tissue that is the cause of the contracture, for a part, if allowed to heal in the position of greatest ease, may be the site of a disabling contracture, even though scar tissue is present in a very small amount. Joints assume the position of greatest ease by reflex rather than by voluntary action. The underlying muscle contracts to relieve the tension on the burned surface area. If, while in this position, the muscle or the tendon becomes fixed in its sheath—and a very slight amount of exudate in either may be sufficient to cause it to do so—the contracture is continued by the connective tissue, though not primarily caused thereby.

The prevention of the contracture would be better than its cure, but prevention may

From the Department of Surgery, St. Louis University School of Medicine.
Presented before the Clinical Congress of the American College of Surgeons, New York, October 17-21, 1933.

not be possible. Theoretically, since the contractures follow burns chiefly on the flexor aspects of joints, all that is needed to prevent contracture is the continued immobilization of the part in hyperextension during healing and in complete flexion for a burn on the extensor surface. In treating burns of adjacent sides of fingers or toes, the fingers would be held widely separated, and for the burn in the axilla it would only be necessary to hold the arm in complete elevation, or at least in complete abduction during healing.

No matter what the treatment may be in theory, in practice one is obliged to have regard for the comfort of the patient and the feelings of his friends. Even though one may begin the treatment of an extensive burn with a full understanding of the need for such safeguards and with a zeal for carrying them into execution, his best efforts are often the cause of increased discomfort and complaint, his ingenuity and his patience are taxed beyond capacity, and, finally, his convictions yielding to his compassion, the doctor takes the easiest way and the part heals in the position of greatest ease.

The immediate treatment of the burn will do a great deal toward shortening the time in the hospital lessening the suffering and diminishing the late contractures. Just as soon as shock is past the patient or the part should be anesthetized—and never with a drug which irritates the kidneys—and the burn should be cleaned and sterilized like any other wound, all dead tissue cut away, and the surface

Fig 1. A splint that keeps fingers apart

Fig 2 A, The hand has been burned and is unsightly. The first 2 fingers and thumb are webbed. B, The amount of scar removed. C, The hand is in a pocket to cover part of the back of the hand, a separate compartment for each finger. D, Final result. E, The skin is freely movable and can be pinched up like normal skin.

sprayed with 5 per cent aqueous solution of tannic acid at least twice an hour until the crust (coagulum) forms. Thereafter the injured part or the patient is kept naked under the warm tent and made comfortable. After about 3 weeks, or whenever the crust is loosening at the edges, the crust is to be removed and warm hot boric packs applied for a few days when skin grafting should be begun.

Early skin grafting is conducive to a more rapid healing and anything which does this will lessen the contracture. Of all types, the simplest to do is the Reverdin procedure and it can be begun almost as soon as granulations are first seen. It possesses this great advantage that no regular operation is needed. A few grafts may be set at each dressing and by sticking the graft in an oblique slit in the raw surface (the method, I think, of John Staige Davis) one's efforts give excellent results. The Thiersch and the Wolf grafts never have much chance as long as there is pus present, and they require an operation but serve well on sterile wounds.

About the best apparatus for the burned hand is some form of the banjo splint. I do not remember who first devised it and the method of using the finger nails to aid in the holding of the fingers in an extended position, but certainly it is most satisfactory (Fig 1).

When the wrist is burned all the way round, a similar device is used, but this is part of a wire frame splint which fits forearm and arm. Whatever apparatus is used it is much better if it does not touch the burned area and, of course, it must not press on any part of it. Any apparatus will somewhat interfere with the dressings, but one should manage to change the dressings without removing the apparatus. The changing of dressings now is never the ordeal it once was. The open treatment has almost entirely abolished them during the early period, and cellophane, rubber strips, and the olive and cod liver oils have robbed the terror from those dressings necessary later.

The contractures about the hand are like those elsewhere, either of flexor or extensor

CONTRACTURES DUE TO BURNS

W T COUGHLIN M.D., F.A.C.S., St. Louis Missouri

A CONTRACTURE is an abnormal shortening of the soft tissues whereby skeletal structures, and often the adjacent soft parts as well, are drawn into and fixed in abnormal position, so that the form is disfigured and the function interfered with. It has long been known that scar tissue contracts as it gets older, and all have noticed that those wounds which healed the most rapidly left the least scar.

Burns take longer to heal than wounds due to mechanical trauma, and almost all those of the third degree suppurate. The pyogenic process is an additional source of irritation to the already injured tissues and a greater production of new connective tissue occurs. Also, these injured tissues require a longer time to heal because not only have surface cells been immediately destroyed, but those directly below have been so seriously injured that they soon die, while those remaining viable are injured in decreasing degree of severity from the surface to the depths where normal tissues remain. Such injured cells cannot respond to the injury until they recover their vitality.

But it is not alone the amount of connective tissue that is the cause of the contracture, for a part, if allowed to heal in the position of greatest ease, may be the site of a disabling contracture, even though scar tissue is present in a very small amount. Joints assume the position of greatest ease by reflex rather than by voluntary action. The underlying muscle contracts to relieve the tension on the burned surface area. If, while in this position, the muscle or the tendon becomes fixed in its sheath—and a very slight amount of exudate in either may be sufficient to cause it to do so—the contracture is continued by the connective tissue, though not primarily caused thereby.

In treating burns of adjacent sides of fingers or toes, the fingers would be held widely separated, and for the burn in the axilla it would only be necessary to hold the arm in complete elevation, or at least in complete abduction during healing.

No matter what the treatment may be in theory, in practice one is obliged to have regard for the comfort of the patient and the feelings of his friends. Even though one may begin the treatment of an extensive burn with a full understanding of the need for such safeguards and with a zeal for carrying them into execution, his best efforts are often the cause of increased discomfort and complaint, his ingenuity and his patience are taxed beyond capacity, and, finally, his convictions yielding to his compassion, the doctor takes the easiest way and the part heals in the position of greatest ease.

The immediate treatment of the burn will do a great deal toward shortening the time in the hospital, lessening the suffering, and diminishing the late contractures. Just as soon as shock is past the patient or the part should be anesthetized—and never with a drug which irritates the kidneys—and the burn should be cleaned and sterilized like any other wound, all dead tissue cut away, and the surface

Fig. 1. A splint that keeps fingers apart.

Fig 2 A, The hand has been burned and is unsightly. The first 2 fingers and thumb are webbed. B, The amount of scar removed. C, The hand is in a pocket to cover part of the back of the hand, a separate compartment for each finger. D, Final result. E, The skin is freely movable and can be pinched up like normal skin.

sprayed with 5 per cent aqueous solution of tannic acid at least twice an hour until the crust (coagulum) forms. Thereafter the injured part or the patient is kept naked under the warm tent and made comfortable. After about 3 weeks, or whenever the crust is loosening at the edges, the crust is to be removed and warm hot boric packs applied for a few days when skin grafting should be begun.

Early skin grafting is conducive to a more rapid healing and anything which does this will lessen the contracture. Of all types, the simplest to do is the Reverdin procedure and it can be begun almost as soon as granulations are first seen. It possesses this great advantage that no regular operation is needed. A few grafts may be set at each dressing and by sticking the graft in an oblique slit in the raw surface (the method, I think, of John Staige Davis) one's efforts give excellent results. The Thiersch and the Wolf grafts never have much chance as long as there is pus present, and they require an operation but serve well on sterile wounds.

About the best apparatus for the burned hand is some form of the banjo splint. I do not remember who first devised it and the method of using the finger nails to aid in the holding of the fingers in an extended position, but certainly it is most satisfactory (Fig 1).

When the wrist is burned all the way round, a similar device is used, but this is part of a wire frame splint which fits forearm and arm. Whatever apparatus is used it is much better if it does not touch the burned area and, of course, it must not press on any part of it. Any apparatus will somewhat interfere with the dressings, but one should manage to change the dressings without removing the apparatus. The changing of dressings now is never the ordeal it once was. The open treatment has almost entirely abolished them during the early period, and cellophane, rubber strips, and the olive and cod liver oils have robbed the terror from those dressings necessary later.

The contractures about the hand are like those elsewhere, either of flexor or extensor

Fig. 3 For dorsum or palm the double pedicled flap is safest. Its pedicle can not become twisted or linked. A Note how the flap has been cut a little at a time until it is ready to be entirely separated. B The plaster-of-Paris does not give quite enough support. The flap should bear no weight.

type and either may be quite disabling. When the hand is burned in infancy or early childhood and repair of the ensuing contracture neglected or deferred, it must not be forgotten that the involved bones and joints will never develop normally, and that no procedure undertaken after the child has grown up can ever yield such good results as can be obtained when reconstruction is begun as soon as possible. And it is not only the changes in development that occur. Even in adults the joint that has long occupied an abnormal position cannot be restored to its normal position by cutting away the scar. The ligaments on the flexor side become so shortened that they prevent complete restoration and certain intra-articular changes often occur which still further prevent a return to normal. Therefore, all contractures should be treated early.

The skin alone is hardly ever the only tissue involved in the scar. The fascia is, as a rule, the one which causes most trouble, although occasionally muscle shortening may call for a tenotomy, or articular ligaments may have to be cut. In those cases wherein joint changes have occurred, it is better to get good, loose, soft parts first to replace those that were shortened and then attack the joint. The reason is that in flap operations suppuration is not very uncommon, and when joints have been opened this will most likely lead to total ankylosis if suppuration should occur.

How to treat the particular case must always be the chief question. No set rule will

Fig. 4 A The flap is long enough to cover both dorsal and palmar aspects. B After it has adhered to the dorsum it is cut free above and allowed to fall down. The flap being attached to the palmar aspect.

do for all. For some of only slight magnitude a simple removal of the skin scar followed by simple, thick, Thiersch skin graft will do, or perhaps by a whole thickness skin graft. These methods of repairing surface defects have much to recommend them and will always, I think, have a large place in surgery. I feel, each time I use one, that I am performing a new experiment because it has happened repeatedly in my practice and in our surgical service that these grafts have often healed in perfectly and then some time after the eighth or tenth day have begun to die from the surface inward, sometimes the entire graft has been absorbed, and in others absorption ceased before the glandular epithelium has been entirely destroyed. In either case the result was far from good. Then, too, there is the ever present possibility of infection, so many actually take part in an operation besides the patient. And the Thiersch or Wolf skin graft to be successful must be sterile from first to last.

In most instances it is desirable to have fat between the skin and the underlying structures. That is one reason why almost every one has fat so placed. After removal of the scar in those severe contractures about the hands, the feet and the neck, it is highly desirable to have the replaced skin in such condition that it is movable over the under

Fig 5

Fig 5 Flexion contracture of elbow can be benefited by the Z-incision (Fig 6 A, B, C), the division of the bicipital fascia and tendon lengthening (Fig 6 D, E). A transverse uncovered area may remain just in front of the joint (Fig 6 F). A flap from the side at the elbow level with its base forward suffices to fill this (Fig 6 G, H).

Fig 6 A, B, and C illustrate the Z-incision. D and E, The flaps have been turned back and a tendon-lengthening done. F, On straightening out the elbow, there is always a transverse area left uncovered after the flaps have been sewed into their new positions. G and H, Such

Fig 6

a defect at the elbow is easily covered by a flap from the side, base forward

lying parts and these are mobile under the skin. This is possible only if a layer of fat, or loose areolar tissue, lies under the skin. All the normal fat and areolar tissue have been destroyed and removed. The best method for such reconstruction is by some means of a flap.

When the scar is on the dorsum of the hand, fingers, or wrist, the new parts for repair of the lesion are got from the anterior part of the abdomen or thigh, for the repair of a palmar lesion of hand, fingers, or wrist, from the patient's back or buttock. When fingers are to be covered, separate compartments are made for each finger (Fig 2 C). One should be sure the compartment is larger than the finger, otherwise death of the finger may follow. Or, if the tip of a finger is brought out through a slit in the skin, the slit must not be made so small that sloughing of the finger tip ensues. Again, the fingers are sometimes *sutured in*. This is dangerous as well as painful and hardly ever necessary.

A bit of adhesive to the exposed tip will do. A suture has been tied around the finger and the finger has sloughed. Whole thickness grafts or Thiersch grafts, either thick or thin, do not give such good finger covering (in the author's practice) as those made by means of the flap. All excess fat can be removed easily when necessary and under local anesthesia. The result is a skin covering which is joined to the deeper parts, or separated from these by a layer of loose connective tissue and the skin moves freely on the deeper parts and is not so subject to trauma (Fig 2 E).

When only dorsum or palm is to be cared for the double pedicled flap is safest and its pedicle cannot become twisted nor kinked as can that of the single pedicled one (Fig 3). The beginner usually makes it too thin or fastens it to the hand too tightly and sloughing occurs across the middle with total loss. This is a great calamity. It can be avoided by having it wide enough and long enough so

Fig 3 For dorsum or palm the double pedicled flap is safest. Its pedicle can not become twisted or kinked. A Note how the flap has been cut a little at a time until it is ready to be entirely separated. B The plaster of Paris does not give quite enough support. The flap should bear no weight.

type and either may be quite disabling. In most instances it is desirable to have fat between the skin and the underlying structures. That is one reason why almost every one has fat so placed. After removal of the scar in those severe contractures about the hands, the feet and the neck, it is highly desirable to have the replaced skin in such condition that it is movable over the under

Fig 9 A, Six months after accident B, Flaps have been wheeled upward and inward after excising the scar below the jaw C, The head is dressed well back D, A flap from the arm (Taghiacozzi) is used to make the lower lip E, But lower lip and chin are still attached to neck A tubed flap (Gillies) is in the making F, The tubed flap has been swung up and is going to replace all of the scar reaching from chin to chest G, The flap has been used twice (note above and below) and is now being used the third time Note lateral view of neck and chin H, This shows what the years have done for him, age 23 Could be much improved by retouching but he "hasn't time"

(Fig 6 F) A flap from the side at the elbow level with its base forward suffices to fill this (Fig 6 G, and H). Such a flap should be at least 2 full inches across at its tip and not less than 3 inches wide at its base. If one has not had experience with this flap he had better begin the making of it before touching the arm. By fastening a piece of cloth to the patient's side and laying it across the arm in front of the elbow on the wound side, he can get some idea from where the flap should be lifted, where the base should remain attached, and where the apex should be. Its outline can then be scratched on the skin and, beginning at the tip, 2 inches of it can be lifted the first day, and replaced and lifted another inch or so in 3 or 4 days. This is repeated until the whole length has been lifted up. It will now be surely viable when transferred to the arm. Closing defects left on the wall of chest or abdomen is usually a very easy matter if one undercuts the superficial fascia and uses strong relaxation sutures.

Cutting a flap free may sometimes be followed by loss of the flap, the part trans-

planted not having sufficiently healed on. This does not happen if clean healing has occurred and if the pedicle has not been cut before 15 days. Trying to hasten the procedure is not always the best way to secure success, and if there is suppuration one had better make sure by waiting at least 3 weeks. By constricting the pedicle with the fingers and watching for color change in the flap, one can tell when the flap becomes viable, for then constriction of its pedicle causes no change of color. When there is any doubt as to the viability of the flap the pedicle or pedicles should be severed slowly. By cutting a little every day or two, Nature seems to make the blood supply answer the demand (Fig 3 A).

A very disabling contracture is that which holds the arm to the chest wall after a burn involving the axilla. The two shown (Fig 7 A, and C) are quite extensive. For those of only slight extent the zigzag incision as in Figure 6 A, B, and C will do. Even a skin graft through a perforation in the middle of the base of the web will suffice. A perforation without a graft allowed to epitheliate through

Fig. 7 For those which involve the upper third of the arm or more a flap of skin and fat gives the best result

B and C Notice the distance that the tip of the flap has had to travel

that the hand can easily be passed under it and then slid up and down for an inch either way. It need not make an exact fit but ought to be wider than the area to be covered. If it is tight at the end of the operation, it will be better to loosen it at that time than later. It is important to have fat enough attached to the flap, and less than half an inch of fat is bad for a beginner. If there is too much fat it can always be removed later, but if too little is left attached to the flap, this will probably die. Another thing the beginner forgets is that such flap sling or pocket must never bear or carry the weight of the hand as a sling does if the patient sits up or goes about. There should be no pressure or tension on a flap (Fig. 3 B).

Sometimes there is scar both on palmar and dorsal aspect of hand or wrist. In these much

time and suffering can be saved by making the same flap do for both surfaces (Fig. 4 A, B). After it has healed on 1 surface the lower end of the pedicle is cut free and the hand rotated 45 degrees, pronated or supinated as the need may be. The scar on the border of the hand is removed and the flap is lengthened and fastened down to this. After another week or 10 days the flap is cut entirely free and long enough to cover the surface remaining to be denuded.

The flexure contracture at the elbow (Fig. 5) can be much benefited by the Z incision, the removal of underlying scar (Fig. 6 A, B, C), the probable division of the bicipital fascia, or even more of the deep fascia and a lengthening of biceps tendon (Fig. 6 D, E). I think a transverse uncovered area just in front of the joint will almost always remain

Fig. 8 A Something must be done at once in order to allow the face and jaws to develop. B A flap is brought from under the chin and the lip and upper part of cheek are unrepaired. C A sive flap brought from patient's back. Note zigzag line of scar from lip down to chin. A straight line scar will shorten and pull the lip down later. D This is how she has grown up.

Fig 11 A, Patient burned 9 years previously and operated upon elsewhere B, A flap from the back, after being cut free at its lower end, is drawn up many times daily toward the position it is going to occupy, until it can

retain its color It is then ready to apply. C, All of the scar tissue between the surface and the hyoid bone is cut through and the flap is sutured into the raw area Retouching later can make it look much better

I have used this latter kind of flap a good deal for contractures of the lower jaw and I like it better the more I use it Many of these contractures follow burns in childhood (Fig. 8, 9) and something should be done at once, for as the child grows, skeletal deformities

will occur involving the lower jaw, upper jaw and spine and these cannot be corrected afterward

Here again the treatment must vary with the extent of the burn. The zigzag incision (Fig 6 A, B, and C), the thick Thiersch graft

Fig 12 A A whole thickness graft at the end of 5 days It is changing from blue to pink B, the same, 5 days later No infection C, The same Healing has occurred but scar

is still present D illustrates a lateral view of the same patient This has never occurred with any of our pedicle grafts

Fig 10. A and B Condition after treatment with whole thickness graft 3 years previously. C The flap has been raised from the back to conceal the scar. The scar unsightly at first, can be narrowed a little at a time by the

method of New if this seems desirable. D, E, and F illustrate the condition of the patient 3 months later when she returned to the hospital to have a small portion of the flap removed.

along a seton, as the pierced ear does, and then cutting through from this opening to the surface will do well enough when the web is thin and small, as in the case of web fingers. For those which involve the upper third of the arm or more, however, I think a flap of

skin and fat gives the best result. It may be that the flap must come from some distance as in Figure 7 B and C. If so, it may be better to raise it in several steps. At times, indeed so much is burned nearby that nothing short of a tube pedicled flap (Gillies) will do

or the whole-thickness graft may do for the small shallow burns, but they are a waste of time with the more severe cases (Figs 10, 11, and 12). For boys and men sometimes it is very convenient to throw in a flap from good skin near by, in them a scar more or less is of no moment; but for the girl one ought to consider the scar left after raising a flap and if possible keep it out of sight.

The tube-pedicled flap from the back is very satisfactory. It may be that it isn't wide enough to cover the whole area when it is unfolded. This must be foreseen and it can be made long enough so that it may be used again and again, as many as 3 times if necessary (Fig 9 F, and G). Not only this, but it can actually be stretched and made long enough to make up for a certain deficit (Fig 13 C, and F). In this case (Fig 13 D) we lost the open part of the flap because of kinking of the tail on the second night. The patient turned while asleep. What remained was too short to reach and too narrow to cover the

defect. Extension was at once applied and the patient was shown how to increase or decrease the pull and the direction. In about 6 months it reached almost to the other ear and we used it twice (Fig 13 C). In some others we have lengthened the pedicle by hanging a weight on it by day and using the elastics at night. The patients learn to apply these themselves and may telephone and return when ready. One objection is the added time, but this doesn't outweigh the many advantages.

One can get a flap from a closer area and without tubing the pedicle as shown in Figure 14. In this case time was of prime consideration. A large flap was lifted half way up the denuded area, Thiersch grafted, and the flap replaced. In 4 days the remainder was raised and grafts placed under it. At the end of 8 days from the beginning the flap was swung into place and healed *per primam*. It was necessary for the patient to stay in the hospital only 23 days.

Fig. 13. A and B. Patient had been operated upon elsewhere. Burned at 5 years of age. C and D. The flap is being lengthened. It was finally long enough to enable us to use it twice. E. A plaster of Paris cast is applied to prevent

another catastrophe turning of the head or kinking of the pedicle. F. To illustrate the manner of stretching the flap and the manner of gradually bringing it to its new bed. G. As he left us.

of the bed has already been skin grafted. D and E show the scarring and the appearance some time afterward. This was one of the quickest repairs. 23 days.

eral surgeon, fracture surgeon, bone and joint surgeon, orthopedist, or what not. It is fundamentally important that the surgeon, who is best prepared to treat fractures, should treat the injuries of our race. They are those who have given of themselves and who are willing to continue to give service and time in order to study and prepare themselves to bring back the disabled individual to his normal capacity as quickly as possible. Names should be disregarded, a common cause—the individual who has been injured—is to be considered primarily. “Disown not your own offspring, yet be not disavowed by your progeny.” This may well be the attitude of surgeons toward those of special groups who attempt to cast out the parent body. They have forgotten or do not know to whom they are indebted for the present high position of the surgeon in relation to fractures. If we were to think in terms of one of Shakespeare’s great plays, the surgeon might be compared to King Lear, who provided for the offspring and then was cast aside as unfit. This seems to be the attitude of some branches of surgery today toward the general surgeon.

FRACTURE SURGERY

Let us consider surgery as the application of one’s knowledge of anatomy for the relief or cure of a pathological condition. Let us remember, too, that today’s axioms were mysteries beyond the horizon of yesterday. The horizon had enshrouded the x-ray, bacteriology, and anesthesia. Therefore, surgery could not progress. The evolution of knowledge had not reached out into the field so clearly defined for us today. Surgery of fractures had to stagnate.

With all of our good fortune have we attained the heights which we should have, or have we followed too closely the dictates of the past? Having defined surgery as the application of one’s knowledge of anatomy for the relief or cure of a pathological state, we cannot help but think of surgery as manual in its conception. Fracture surgery is not different from other surgery. It is distinctly, not merely, the treatment of broken bones.

The treatment of fractures implies the utilization of the best knowledge of the sur-

geon, as well as the application of the minute knowledge of our forefathers of surgery. They passed from the degraded position of “barber surgeon,” through the stage of consort to “sack-em-up men,” until today they are the high priests of the suffering, the sculptors repairing the finest work of the Great Architect.

Who were the ancestors of the fracture surgeons of today? In this survey of the evolution of fracture treatment we have elected to begin with the writings of Guy de Chauliac. No matter where one attempts to make his initial investigation he will find literature of value antedating the entrance of his earliest hero on the scene. If we were to accept Hippocratic writings as a starting point, we would become disillusioned immediately. In an epitomy of Hippocrates and Galen, published in 1846, by Cox, we find:

“We cannot in full force of the term admit, that the title of Father of Medicine is justly his due without encroaching on the rights of others, especially since it is incontestably proved by many that these treatises, we admire as his, have really emanated from other sources.”

Hippocrates would not have claimed originality for himself.

“People rather admire what is new, and what is strange they prefer to what is obvious” (Hippocrates).

As a warrant for electing to begin with de Chauliac, I quote from Desault:

“Celsus only copied Hippocrates, adding nothing to his mode of practice. No new method distinguished the surgery of the Arabians. It is necessary to come down to the time of de Chauliac before we meet with the method which is almost universally adopted at present.”

What were the diagnostic signs by which the fathers of surgery recognized fractures, and what were the principles of treatment? de Chauliac taught:

“The signs of fracture are manifest to the senses. If the hand is placed on the region and touches the limb, it finds the part of the bone separated one from the other, and variable, and the figure of the limb abnormal. In palpating with the hand a crackling is heard in the bone, and pain when the spot is touched, and lack of power to sustain it in place.”

Already the pioneer was teaching the value of inspection, palpation, manipulation, and

THE EVOLUTION OF FRACTURE TREATMENT

ISIDORE COHN, B S, M D, F A C S, New Orleans, Louisiana

THE evolution of fracture treatment has necessarily been a slow process. The story of fractures through the ages is a definite challenge to the industry and enthusiasm of the present and future generations. As we read yesterday's record preserved by faithful historians, we cannot help but marvel at the powers of observation which enabled the master surgeons of the past to diagnose and treat fractures without the aid of modern scientific adjuncts. One wonders at the temerity of surgeons prior to the introduction of anesthesia. How they were able to reduce deformity caused by fractures without the benefit of anesthesia, will always remain a tribute to the heroism of patients. How simple, in a way, this particular great gift has made the management of these cases is not appreciated by our generation.

From Hippocrates through Galen, de Chauliac even down to the latter part of the nineteenth century, there were lengthy discussions about matters which today even a first year medical student would consider primary information. This information was not available to the greatest surgeons of the past, they had to depend on their knowledge of anatomy and of logic, and based on these alone we find great treatises written on the subject as to whether one position or another was better, or whether one splint or another was preferable. To the credit of the ancients we should say without hesitation, that many of the things which are being rediscovered today were utilized by our forefathers, if not entirely certainly in principle and in many instances they all but stumbled on the things which seem so important today.

'Hundreds of the profession have derived their celebrity from our general ignorance of the learning and attainments of Galen by stripping the laurels from his honored brow, from which they unduly

From the Surgical Department, Touro Infirmary and County Hospital

Fracture oration before the Clinical Congress of the American College of Surgeons, New York, October 17-21, 1938

*wreathed a wreath to place around their own altogether undeserving of it'*¹

Each generation looking back at the history of the past speaks of itself as modern and the older generation as ancient. It is probable that the next generation will think in terms of ours with the same attitude as we look on those of the past. We trust that they will show as much respect for us as we must show to those who preceded us.

Our respect is due to Galen, de Chauliac, Pare, and a host of others who accomplished so much with the only means available, their powers of observation and anatomical knowledge. Their example should stimulate us to emulate them.

It becomes our duty to insist on a greater amount of practical application of the anatomical information which is available.

Our own generation should avoid making use of short cut methods and special gadgets.²

*'The very facilities we possess are among the chief causes of our imperfection. Like the hero in the fable, we lie down in repose in full persuasion that the hours of indolence may be easily regained'*³

It is our duty to teach fundamental principles, as principles alone should guide us in the management of fractures. We will discuss evolution in terms of principle and not in terms of particular apparatus or particular fractures. If we were to attempt to discuss evolution of the treatment of any one fracture it would carry us too far afield. This discussion will be limited to principles which have to do with the diagnosis and treatment of fractures, bacteriological principles, x ray, and industrial developments, which have done so much toward making our present methods possible.

Let us not think in terms of what a man calls himself, whether he calls himself a gen

¹The writings of Hippocrates and Galen. Epitomized from the Latin and translated by John Redmond Cose. Published in Philadelphia, 1840.

²Magnus on Paul. Fundamentals versus gadgets in the treatment of fractures. Fracture Orations. Delivered before the Clinical Congress of the American College of Surgeons, 1935.

femur, and the shortened and retracted appearance of the arm in fractures of the humerus are generally unmistakable evidence of the nature of the accident. The manner in which the patient inclines his head and supports the elbow and forearm in fractures of the clavicle, is too significant to be overlooked by anyone who has ever witnessed it. The peculiar aspect and the attitude of the broken thigh, conjoined with the utter helplessness of the muscles, or the absence of voluntary power are signs which seldom admit of misinterpretation."

It is interesting to compare the careful inspection, palpation, mensuration, advocated by Heister, Cooper, Malgaigne, Desault, Hamilton in 1866, and Gross in 1882, with the hurried advice, "have an x-ray picture taken," so often heard today. These instructions might well serve as a summary of all that was known up to 1895. To our diagnostic armamentarium was added the x-ray in 1895 by William Roentgen.

A review of the literature from de Chauliac to the latter part of the nineteenth century, reveals several salient facts. (1) Diagnosis was based on clinical signs and symptoms, pain, loss of function, crepitus, abnormal mobility, and physiognomy of the part, (2) a knowledge of anatomy was depended upon; and (3) painstaking observations were made. At this point they were forced to stagnate. For nearly 600 years no progress could be made.

Like a beacon across a storm-tossed sea, the light of opportunity burst upon us with the advent of the x-ray. What were some of the results of the introduction of the x-ray? It no longer was necessary to resort to manipulation, for the purpose of eliciting abnormal mobility and crepitus to satisfy one's self that the injured individual had a fracture. In fact, it then became the duty of the teacher, to insist that the traditional crepitus and preternatural mobility should not be sought. Unfortunately, diagnostic acumen seems to have fallen to a low ebb. The surgeons trained before the advent of the x-ray merely used the x-ray as an adjunct and as an essential, added factor, and they trained their students to do likewise.

The powers of observation from which one could note the loss of active motion, the change in the attitude of the limb, plus local-

ized pain, obtained by light palpation, enabled the clinician to indicate nearly accurately where the fracture was and the x-ray was and is used by this group to confirm the diagnosis. For another group, who would take the "royal road," an x-ray is ordered immediately, and action taken on the result reported by the radiologist.

This innovation laid upon us certain obligations, obligations which I fear we have not altogether accepted. The x-ray provided us with a rapid means of diagnosis, but it also directed that we evaluate data not heretofore available, and it clearly indicated that all stored up knowledge gained by experience should not be cast aside. The new data consisted primarily of the visual image. It soon became evident that the visual image of bones varies with age. It became apparent at once to Poland, that a correct interpretation was needed of the appearance of epiphyses at all ages up to adult life so that the normal would not be mistaken for the abnormal. We soon learned that fractures through the epiphyseal lines could not be diagnosed by the x-ray in young children.

In the early part of the paper a statement was made that the ancients all but stumbled on some of the things which seem so important today. One of these has to do with the so called epiphyseal separations. In 1859 Malgaigne stated

"I rank among fractures these lesions (epiphyseal separations), which some modern authors would consider as distinct from them."

According to Malgaigne, Bertrandi established by dissection the existence of so called separations of the epiphyses. Of course, he had no x-ray, therefore could only philosophize about the nature of the lesion, but he did say:

"When the solution of continuity is on a level and in the same direction with the epiphyseal cartilage the presumption is in favor of the decollation, but certainly can only be arrived at by an autopsy. Consequently aside from the complications the prognosis is the same as for the ordinary fracture near joints."

In 1866 Hastings Hamilton stated:

"Epiphyseal separations we shall not hesitate to class with fractures, and to submit them to the same rules of nomenclature."

mesuration, the importance of pain, change in the axis of the limb, loss of function, abnormal mobility and crepitus

As one further reviews the literature he finds that he has to go down the ages to 1758, to the epoch making work of Heister

'It is no difficult matter to examine fractures of the bone

1 By the eye when the injured part is apparently shorter than the sound, or when you see that the patient cannot make use of it

2 By the touch when you perceive a preternatural inequality of the bone or that it bends in a part where nature never intended it should, and here by the way, we must recommend it to surgeons if it be possible to fix the patient immediately at the first searching of the fracture where he is to lie during the course of the cure

3 By the ear when we hear the ends of the broken bones crush against each other upon moving the limb

In 1832, Sir Astley Cooper stated

Some of the symptoms of fractures are nearly conclusive. The crepitus, the change in the form of the limb and the shortening of it are circumstances common to the most certain information

America's own William Gibson, in 1832 believed

'In general crepitation is more to be relied on than any other sign, and is an almost certain indication of fracture. Added to this there is usually more or less deformity, pain, swelling, inability to use or move the limbs'

Malgaigne, speaking for French surgeons in 1859 stated

The phenomena to which fractures give rise are cracking heard by the patient at the time of the accident, pain, loss of power in the limb, confusion of the skin, swelling or subsequent preternatural mobility at the seat of the injury, deformity from displacement of the fragments and crepitation. If the finger be passed slowly and carefully over the whole length of the suspected bone unless it has been subjected directly to external violence the absence of all pain and pressure will prove its integrity, on the contrary the existence of pain more or less severe at a circumscribed spot would afford strong presumption of a fracture. More than once from this sign alone I have ventured to diagnose a fracture

This attitude on Malgaigne's part of recognizing the importance of localized pain is probably one of his greatest contributions. If that particular teaching were more generally

followed there would be fewer patients treated today for so called sprains

In 1866, Hastings Hammon published his remarkable work, the first of its kind in the United States. From this the following is quoted

'In proceeding to establish a diagnosis in any case the surgeon should sit down quietly and patiently with the sufferer, so as to inspire in him from the first, the confidence that he is not to be hurt or at least not unnecessarily

'He ought then to inquire of him minutely as to all the circumstances immediately relating to the accident in order that he may determine as nearly as possible its cause which alone to the experienced surgeon often affords presumptive if not conclusive evidence as to the nature and precise point of the injury

From this, he should proceed to examine the discolored limb removing the clothes with the utmost care by cutting them away rather than by pulling and when completely exposed should notice with his eye its position its contour the points of abrasion discoloration or of swelling, and not until he has exhausted all of these sources of information ought the surgeon resort to the harsher means of touch and manipulation

Nor will his sensations guide him to the point of fracture by any other methods so accurate as when the patient being composed and his muscles at rest he moves the fingers lightly along the surface of the limb pressing here and there a little more firmly according as a trifling induration or elevation may lead him to suspect this or that to be the point of fracture

The limb may now be measured with a tape line and compared with the opposite limb having first marked with a soft pencil or with ink the several points from which the measurements are to be made

Finally if any doubt remains the limb must be firmly but steadily held while the necessary manipulations are performed for the purpose of ascertaining the existence of mobility and of crepitus

Samuel D. Gross, or the elder, in 1892 stated

There are only 3 symptoms which are at all reliable evidence of existence of fractures, namely crepitation, deformity and preternatural mobility. The co-existence of these symptoms is unmistakably denotive of the nature of the accident. Too much stress cannot be placed upon preternatural mobility as a sign of fracture. Next to crepitation it is unquestionably the most important diagnostic symptom

The physiognomy, or general expression of the affected part often affords valuable diagnostic aid. The deformity for example of the hand and wrist in fractures of the lower extremity of the radius the eversion of the toes in intercapsular fractures of the

"The general treatment of fractures embraces three principal indications. The first is to reduce the pieces of bone into their natural situation (Cooper favored immediate reduction) The second is to secure and keep them in this state. And, the third is to prevent any unpleasant symptoms likely to arise and to relieve them when they have come on."

The interest and enthusiasm of the surgeons of that generation to obtain every available bit of information, so that they could improve themselves in the management of fractures, may be well appreciated by visiting the collections of specimens made by Cooper, Hunter, and others, to be found in the great museums of Great Britain

Strange as it may seem, anatomical knowledge and surgical progress were inhibited by law. Stranger still is the fact that crime paved the way for the study of anatomy. Prior to the Warburton Act of 1832, which legalized the study of anatomy in England, the only subjects legally available for dissection were the bodies of criminals who were sentenced to be "dissected and anatomized." The teachers of anatomy at that time had to purchase bodies from "resurrectionists." These unscrupulous bands of grave snatchers carried their nefarious occupation farther and murder became an active business. One visiting Edinburgh today will see reminders of the activities of this band. The mort-safes in Gray Friars Cemetery bear mute testimony to the work of the "sack-em-up men." The life and usefulness of some of the great anatomists of that day were blasted by public indignation which was aroused by the proof of their association with the purveyors of human bodies. Nevertheless, the desire for knowledge and the hope of rendering service forced the courageous group of surgical anatomists to continue their relations, with resurrectionists

"Sir Astley Cooper's usefulness to the world was based on his profound knowledge of anatomy, and this was gained by the careful dissection of bodies, which were supplied him by the resurrectionists. Thus did the end justify the means."¹

The modern slogan, "Crime does not pay," was proved when Burke, Bishop, and Williams, were convicted and sentenced to death. Fol-

lowing their execution, public sentiment was sufficiently aroused to permit the passage of the act legalizing anatomical study. An act, which was thought then as now by some as a desecration, has proved to be a consecrating link of the past with the present and future welfare of the human family.

Knowledge of anatomy substitutes safety for boldness and daring. Cooper like many of his contemporaries realized difficulties incident to the management of certain fractures and the utter hopelessness of obtaining good results in certain fractures. This spurred him on in his desire to obtain specimens for study. From a report by Sir Astley Cooper, "On Fractures of the Neck of the Humerus," the following is quoted:

"Let the surgeon do what he will, the head of the humerus will probably remain in the axilla, and the upper motions of the arm will be in a considerable degree lost."

Astley Cooper proved himself more than an anatomist, more than an operator, he was a true surgical philosopher. The advice contained in the following admonition should be heeded by all who believe in the dictum that we should be generous to others and critical of ourselves, for therein lies the attitude which should characterize the unselfish seeker of knowledge

"These cases should teach the members of our profession to be kind, generous, and liberal toward each other, and not to impute to ignorance or inattention that which is the result of a generally incurable accident. It too often happens that when every trial has been made to restore the parts and without success, the patient goes to some other surgeon to whom he shows his arm, and points out its uselessness and want of motion. A jealous and illiberal medical man might say, 'Yes, this is a dislocation which has not been reduced. I wish I had seen it at the first, but now it is too late for a successful attempt to replace it.' However, every intelligent well informed surgeon will now confess that no knowledge or exertion of skill could have prevented the deformity and loss of the natural motion which results from this formidable accident."

This eloquent plea is not only the philosophy of a generous man, but it is almost like a crying aloud in the wilderness for more help in the diagnosis of fractures. Such came with the advent of the x-ray.

¹Ball, James Moore. Sack-Em-Up Men. Edinburgh: Oliver & Boyd, 1925.

The discussion still goes on. It is certainly to be hoped that in the near future we will recognize that all epiphyseal separations are in reality fractures. I believe we cannot escape this solution to the problem. We believe that the prophetic statement of the older surgeons on this point might well be adopted and that the term, "epiphyseal separation," be deleted from our surgical nomenclature.

It also became apparent that the hypothetical conditions, reverently spoken of as "sprains," were in most instances fractures. It is devoutly to be hoped that this antiquated term will soon cease to occupy the position of prominence which it does at present.

TREATMENT OF FRACTURES

When considering the principles involved in the treatment of fractures, one is confronted by a situation which is well summed up in the writings of John Bell, 1826:

'Ask a young man who has studied his profession faithfully what he would do with a fractured limb? He cannot tell. Ask the same question of one who has practised it well and sensibly. He cannot tell how he himself is accustomed to manage a fractured limb. He has no rule or settled methods. Ask the man of books and study what have been the doctrines of old, or what have been the actual improvements of the modern surgeon, he also is at a loss. Theories, bandages, machines, improvements innumerable, he can well remember, but altogether with these recollections this conviction always rests upon his mind that the subject which he has long regarded as the most interesting is the only one which he has vainly endeavored to understand.

'There is no rule or principle yet established: this is almost the only department of practice which has been continually changing without ever being improved.'

In looking back over the literature we find much that we might quote from the masters of the past. Sound advice given by Hippocrates might well continue to be followed by those seeking to improve methods of treatment of fractures.

'Hippocrates tells us that medicine in all of its branches had been long established that they had found out the principle, and the route of discovery of many excellent things which would serve for the discovery of more provided that those who undertook the task were fitted for it, and possessing a knowledge of what had already been done, would pursue a similar route.

de Chauviac taught the following:

"The general treatment of fractures follows the general intentions of wounds and there are 4 principal intentions. The first is to equalize the bone the second to preserve the equalized bone the third to bind it with callus, the fourth to remedy complications. Before all things, one should prepare all that is necessary for the reduction. The necessary things are: Let one have a cradle or suspensory in which the limb will be firmly and evenly placed, a mattress bed on which the patient sleeps and if it is necessary let it be perforated so that he may go to stool a cord hanging over the bed or some other thing for him to catch and help himself when he wishes to go to stool or turn him self."

Here then are the fundamentals which were possible prior to anesthesia, asepsis, and the x ray. When we would flatter ourselves about recent developments in the general management of fractures it should take no more than the above quoted statement of de Chauviac to humble us.

Sound advice, given by Heister in 1759 with reference to treatment of fractures, is the following:

'The surgeon's principal care in fracture is to unite the broken bones to which three things are necessary: (1) That the bone be restored to its natural situation (2) that after the bone has recovered its natural situation it may be kept there by giving it rest, and applying proper bandages, and (3) you are to use proper means to prevent or remedy the disorders that usually attend this accident. The knowledge of anatomy is necessary to perform these intentions.

As early as 1803, Desault was pleading for the application of anatomical knowledge and physical principles in reduction of deformity and the maintenance of the reduction. He says:

'All kinds of apparatus for fractures being nothing but resistances opposed by art to the powers which produce displacement it follows that they should all act in directions precisely opposed to the directions of the powers.

If more attention were paid at the present time to such fundamental anatomical and physical principles involved in this admonition, there would be less necessity for operative procedures in the treatment of fractures.

Sir Astley Cooper, speaking for the English professor in 1832, stated

"The general treatment of fractures embraces three principal indications: The first is to reduce the pieces of bone into their natural situation. (Cooper favored immediate reduction) The second is to secure and keep them in this state. And, the third is to prevent any unpleasant symptoms likely to arise and to relieve them when they have come on."

The interest and enthusiasm of the surgeons of that generation to obtain every available bit of information, so that they could improve themselves in the management of fractures, may be well appreciated by visiting the collections of specimens made by Cooper, Hunter, and others, to be found in the great museums of Great Britain

Strange as it may seem, anatomical knowledge and surgical progress were inhibited by law. Stranger still is the fact that crime paved the way for the study of anatomy. Prior to the Warburton Act of 1832, which legalized the study of anatomy in England, the only subjects legally available for dissection were the bodies of criminals who were sentenced to be "dissected and anatomized." The teachers of anatomy at that time had to purchase bodies from "resurrectionists." ¹Ball, James Moore. Sack-Em-Up Men. Edinburgh: Oliver & Boyd, 1938

The discussion still goes on. It is certainly to be hoped that in the near future we will recognize that all epiphyseal separations are in reality fractures. I believe we cannot escape this solution to the problem. We believe that the prophetic statement of the older surgeons on this point might well be adopted and that the term, "epiphyseal separation," be deleted from our surgical nomenclature.

It also became apparent that the hypothetical conditions, reverently spoken of as "sprains," were in most instances fractures. It is devoutly to be hoped that this antiquated term will soon cease to occupy the position of prominence which it does at present.

TREATMENT OF FRACTURES

When considering the principles involved in the treatment of fractures, one is confronted by a situation which is well summed up in the writings of John Bell, 1826:

Ask a young man who has studied his profession faithfully what he would do with a fractured limb? He cannot tell. Ask the same question of one who has practised it well and sensibly. He cannot tell how he himself is accustomed to manage a fractured limb. He has no rule or settled methods. Ask the man of books and study what have been the doctrines of old or what have been the actual improvements of the modern surgeon, he also is at a loss. Theories, bandages, machines, improvements, innumerable, he can well remember but altogether with these recollections this conviction always rests upon his mind that the subject which he has long regarded as the most interesting is the only one which he has in vain endeavored to understand.

There is no rule or principle yet established. This is almost the only department of practice which has been continually changing, without ever being improved.

In looking back over the literature we find much that we might quote from the masters of the past. Sound advice given by Hippocrates might well continue to be followed by those seeking to improve methods of treatment of fractures.

"Hippocrates tells us that medicine in all of its branches had been long established that they had found out the principle and the route of discovery of many excellent things which would serve for the discovery of more provided that those who undertook the task were fitted for it, and possessing a knowledge of what had already been done, would pursue a similar route.

de Chauliac taught the following:

'The general treatment of fractures follows the general intentions of wounds and there are 4 principal intentions. The first is to equalize the bone the second to preserve the equalized bone the third to bind it with callus the fourth to remedy complications. Before all things, one should prepare all that is necessary for the reduction. The necessary things are. Let one have a cradle or suspensory in which the limb will be firmly and evenly placed a mattress bed on which the patient sleeps and if it is necessary let it be perforated so that he may go to stool a cord hanging over the bed or some other thing for him to catch and help himself when he wishes to go to stool or turn himself.'

Here then are the fundamentals which were possible prior to anesthesia, asepsis, and the x ray. When we would flatter ourselves about recent developments in the general management of fractures it should take no more than the above quoted statement of de Chauliac to humble us.

Sound advice, given by Heister in 1759 with reference to treatment of fractures, is the following:

The surgeon's principal care in fractures is to unite the broken bones to which three things are necessary (1) That the bone be restored to its natural situation (2) that after the bone has recovered its natural situation, it may be kept there by giving it rest and applying proper bandages and (3) you are to use proper means to prevent or remedy the disorders that usually attend this accident. *The knowledge of anatomy is necessary to perform these intentions.*

As early as 1805 Desault was pleading for the application of anatomical knowledge and physical principles in reduction of deformity and the maintenance of the reduction. He says:

'All kinds of apparatus for fractures being nothing but resistances opposed by art to the powers which produce displacement it follows that they should all act in directions precisely opposed to the directions of these powers.

If more attention were paid at the present time to such fundamental anatomical and physical principles involved in this admonition, there would be less necessity for operative procedures in the treatment of fractures.

Sir Astley Cooper, speaking for the English professor in 1832, stated

The first reference in a text on the subject of fractures to the Listerian method, we find in Gross's work:

"Whether carbolic acid, apart from the other means, recommended by Lister, is really any benefit in the treatment of those injuries is still a mooted question. A modification of the Lister treatment was introduced a few years ago in the New York Hospital by Professor Markoe, and has given most flattering results, only 1 death resulting in nearly 200."

More important, however, than any detail of treatment one can find is the advice of Gross with reference to fractures:

"There is no class of injuries which a practitioner approaches with more doubt and misgiving than fractures. They frequently involve consequences hardly less serious and disastrous to the surgeon than to the patient himself. If I were called upon to testify what branch of surgery I regarded as the most trying and difficult to practice successfully and creditably, I should unhesitatingly assert that it was that which relates to the present subject.

"I certainly know none which requires a more thorough knowledge of topographical anatomy. As for myself I never treat a case of fracture, however simple, without a feeling of the deepest anxiety in regard to its ultimate issue, without a sense of discomfort, as long as I am conscious that despite the most assiduous attention and the best directed efforts the patient is likely to be lame and deformed for life. A crooked limb, whether rendered so by injudicious treatment or not, is an unpleasant sight to the sensitive surgeon, in as much as it continually reminds him of his bad luck or want of success. I do not wish to be understood to say that it is always in his power to cure these accidents without deformity or impairment of function. Such a view would be contrary to experience and common sense. There are many cases of fracture which do not admit of any other results, however attentively or skillfully they may be treated."

The dissatisfaction expressed by Gross, Hamilton, and others led just a few years later to efforts to improve results. There appeared on the scene Arbuthnot Lane who Moynihan said was, "A man whose mind easily moves along new paths." As early as 1865, Lane began operating on fresh fractures, and for this purpose he used wire. His boldness is an inspiring example of an individual with courage to break away from tradition. He at least had the bolstering influence of the epoch-making work of the pioneers who had introduced anesthesia and of those who had paved the way for a clean surgical wound.

Surgical approach to the subject of fracture diagnosis and treatment had reached an *impasse* prior to the time of Crawford W. Long, in 1842, at which time he introduced ether anesthesia. We marvel at the heroism of the patients and the temerity of the surgeons of the past, who with brute force and "blind flying" attempted reduction of deformities following fractures in the days before anesthesia, and before the introduction of the x-ray. We also marvel at the boldness of the surgeons who before Pasteur and Lister attempted operative treatment of fractures.

As early as 1854 we find that Brainard condemned the use of wires and foreign bodies of every description as a means of promoting the formation of callus. He said: "It is a practice not founded on correct principles and is often dangerous." It should be recalled that this statement was made several years before Lister's application of Pasteur's discovery. Brainard however proved the greatness of his mind in the following statement: "Every method of treatment for ununited fractures appeals to experience in proof of its success."

Time marched on and Lane and Lambotte continued their pioneering break with orthodox methods. What reasons did Lane give for his desire to seek a change? From his own works published in 1905, we quote.

"Experience has taught me to regard the statements in anatomical and surgical work with strong suspicion. It was evident that the displaced fragments of a broken bone were never or hardly ever restored to their normal position, and the so called 'setting of fractures' was a myth. I made very extensive inquiries of medical men, and I was satisfied that the teachings contained in the text books, as to the possibility of restoring the form of broken bones, and the satisfactory results of their treatment were absolutely false."

These words of Lane were written in 1905, but he had evidenced his unrest as early as 1885. This was 10 years before Roentgen's discovery of the x-ray.

THE X-RAY

Evolutionary processes go on in the natural order. Man's appreciation of them waits for the unfolding of the secrets in the world about us, and for the practical application of the

We pass from England to France, from 1832 to 1859. In the preface to his treatise on fractures, Malgaigne indicates that his work is the first treatise in the French language limited to the subject of fractures. Malgaigne fulfilled his aim of, "Presenting a resumé of all the doctrines and ideas maintained from the earliest time to our own days, 1859." In vain one searches for a change of method or principle.

A brief resume of Malgaigne's teachings follows.

"The treatment of fractures consists, generally speaking, in the fulfillment of two principal indications. To reduce the broken ends and to keep them in place until consolidation is complete.

The proper time for attempting reduction is a question that has presented itself ever since the earliest time and has been variously solved by practitioners. According to Hippocrates, extension should be attempted on the first or second day. Boyer and Larrey advocated in general immediate reduction and Velpeau also advocated immediate reduction.

Malgaigne concludes

It is indeed the first day that is generally the most favorable.

Anesthesia is not mentioned under the heading of treatment, and the old discussion of when to reduce was revived. On that point Malgaigne was as definite as surgeons of our own day. In Hamilton's epoch making *Treatise on Fractures* in 1806, the first treatise limited to the subject in America, we find several noteworthy contributions. It is the first treatise in which anesthesia is advocated for diagnostic purposes, and for treatment. He says

I do not often find it necessary to resort to anesthetics for the purpose of insuring quietude and annihilating pain in making these examinations, but if the examination is not satisfactory and the diagnosis is important I do not hesitate to render the patient completely insensible.

Hamilton is definitely committed to the plan of immediate reduction.

"Nearly all fractures present 3 principal indications of treatment, namely: To restore the fragments to their place as completely as possible; to maintain them in place; and to prevent or control inflammation, spasms and other accidents. It ought to be regarded as a rule, liable only to rare exceptions

that broken bones should be restored to place as soon as possible after the occurrence of the accident.

His advice with reference to transportation of the injured may well be conceded as a forerunner to the instructions given by our transportation committee, namely, "Splint them where they lie," and "gentleness of handling." Hamilton states

'All that has been said in relation to the propriety of handling a broken limb gently when the surgeon is examining the position and character of the fracture, is equally applicable to the lifting and transporting of the patient to his bed, to the removal of his clothing and to the general management of the limb before it is dressed. Rude or awkward manipulations by which needless pain is inflicted are not simply acts of wanton cruelty but they are sources of inflammation, suppuration and gangrene. It is difficult to state the precise manner in which the surgeon ought to proceed. Much will depend upon the circumstances of the case, something upon one's natural tact and upon the amount of experience, but more I think upon the natural kindness of heart and social education. The man of refinement and sensibility will know instinctively how to proceed and needs no instructions. They who lack these qualities can never learn and it would be quite useless to undertake to teach them. I sincerely wish such men as these latter would find some more suitable employment than the practice of a humane art.

Those who believe that the so called Balkan frame and suspension methods are of recent introduction would do well to note the Jenks fracture bed frame described in Hamilton's text, as well as other suspension frames. The after care of fractures with fracture beds containing provisions for bed pans was advocated by Hamilton, and he describes the Daniels fracture bed with such a provision.

In the section devoted to fractures, by Samuel D. Gross the elder, in his *System of Surgery*, published in 1882, we find the indication for treatment of fractures briefly summed up.

The leading indications in the treatment of fractures are to procure reunion and to prevent deformity. It has been a much mooted question whether as a general principle a fracture should be set as soon as possible after its occurrence or whether time should be allowed for the subsiding of the resulting inflammation. It certainly requires no great knowledge of the nature of the accident to discover that such cases should receive the earliest possible attention.

CONCLUSION

The discussions which have arisen since 1900 with reference to operative or non-operative treatment have had only one objective, to obtain the earliest and safest method of returning the injured to economic efficiency. In order to establish the truth, statistical studies had to be made, since none were available. These were not easily obtained. Statistics, which were presented in the early days, were favorable to one or the other method depending on the source and ability of the surgeons compiling them. It soon became evident that certain fundamental principles had to be applied if the greatest good was to be done. These principles are:

1. In general, conservative treatment applied along anatomical lines was the most successful in the average hands

2. Certain fractures have to be operated upon routinely

3. Direct surgical treatment of fractures should be done only by those qualified by training to operate and equipped with adequate armamentarium

4. Proper hospital facilities are essential

Improvements in x-ray facilities, better surgical technique, and new anesthetic agents have all contributed to the safety of surgery whenever indicated

From the earliest times we find that the masters of surgery taught the value of reduction and immobilization. When to reduce, whether immediately or after variable periods of waiting for the swelling to subside, has provided many arguments. The gist of all discussions at the present time is that attempts at reduction should be made as soon as possible after the accident in simple fractures.

In compound fractures the debate still goes on. Some advocate immediate internal fixation and others direct skeletal traction and suspension. This is a question of experience and not evolution. The evolutionary step is the question of operation as an addition to our portfolio of safe procedures. The safety of this progressive step is dependent upon the

qualifications of the surgeon and the environment provided. This question has been presented admirably by William O'Neill Sherman in a recent fracture oration. It need only be pointed out that direct, operative attack, which resulted from dissatisfaction, was a step in the development of fracture treatment.

In the evolution of the operative procedures by internal fixation many materials have been used and each lauded by enthusiasts. Time alone will answer all of the questions whether absorbable or non-absorbable material should be used, whether autogenous grafts of one kind or another are best; whether grafts are absorbed and act only as a splint and scaffold, or whether they remain permanently; whether one material is irritant, electrolytic, or not. All of these represent the passing show.

The principle of operating in selected cases is, however, a definite stage in the evolution of fracture treatment. Factors, which have made this step possible, are industrial developments, particularly chemical and metallurgical, as well as scientific achievement along bacteriological lines.

It should not be forgotten that fundamental principles of fracture treatment remain the same. They are early reduction and adequate immobilization. The axiom with reference to anatomical knowledge necessary for reduction must not be overlooked.

Will observers in the future credit our generation with progress in principles and practice or will we be charged with having spent our time idly discussing the polemics of who should treat fractures? Traumatic surgery is demanding more and more of our efforts, due to the ever increasing hazardous occupations and modes of transportation. The evolution of the fracture problem depends on continued search for truth and the utilization of all of the aids that scientific achievements place at our disposal for the benefit of the suffering mass of the human family. Let it not be said of our generation that we stagnated, or that we were bound by the adamant force of the authorities of yesterday.

scientific information thus unfolded. Within 1 year of Roentgen's discovery 49 books and more than 1000 scientific and clinical papers were published. The profession had been waiting for someone to lead them from darkness to light. Methods of reduction, which up to the advent of the x ray had been dependent on accurate clinical observation, now had a valuable adjunct. American surgeons, like surgeons in all parts of the world, were quick to realize potentialities of x ray for diagnostic purposes. The effect of the introduction of the x ray on the professional mind is clearly stated by Cattell in 1896:

"No discovery in medicine has equalled its importance since Pasteur, Lister and Koch placed bacteriology on a scientific basis. Who a year ago would have dreamed of being able actually to see the displaced fragments in a Colles' fracture, to set the bone, to dress the arm and then examine the bone again through the wooden splint and bandages, and note whether or not the broken bones had been correctly approximated? The imagination of the reader is left to discover new fields of usefulness for this most wonderful and practical discovery of Professor Roentgen."

On April 8, 1896, in the *Electrical Engineer* published in New York the following announcement was made with reference to the opening of the Post Graduate Hospital X ray Department:

"Doctors to become cathodographers. Cathodography will shortly become one of the regular features of the Post Graduate Hospital, 20th Street and Second Avenue."

The utility of taking x ray pictures in surgery has been demonstrated so often, that hospital authorities have decided to set aside one of the smaller wards for that purpose and they will equip it with Crookes tubes, Puimkorff coils, sensitized plates, and all other paraphernalia of the new art.

According to Glasser this was the first special Roentgen Department in the United States.

Philip Mills Jones, of San Francisco, and Edward A. Tracy, of Boston, expressed the sentiments of various sections of this country with reference to the new discovery and its usefulness.

"With no discovery within my recollection has the immediate and general excitement been so intense. The application of the x rays in medicine has thus far been confined almost entirely to surgical

diagnosis. Fractures and dislocations, though easy of diagnosis, are sometimes very puzzling. No matter what the natural ability, education or experience of the fingers, they may often be at fault, here, we have an agent that cannot err."

"The fractures and dislocations that have been examined with much profit by this means includes almost every large bone, almost every joint in the body, and no man who has availed himself of this aid in such cases will speak of it in any terms save those of the highest praise."

Edward A. Tracy, in 1897, said:

"The application of Roentgen's discovery necessitates the rewriting of the textbooks on fractures and dislocations. Facts, heretofore 'smothered by surmise,' are clearly set forth by the radiographs."

The United States Army made the x ray an integral part of the Army medical equipment before 1898. In an article by W. C. Borden, published under the direction of the Surgeon General, George M. Sternberg, we read:

"Soon after the discovery by Professor Roentgen the Surgeon General of the Army supplied Roentgen ray apparatus to several of the larger post hospitals. On the outbreak of the war with Spain and the establishment of the general hospitals, the most prominent and important of these hospitals and the three hospital ships, Relief, Misouri and Bay State, were supplied with similar appliances. The use of the Roentgen ray has marked a distinct advance in military surgery."

One can say that the golden age of fracture diagnosis and treatment was born with the advent of the x ray. After the advent of the x ray reduction could be carried out with an accuracy not possible before. Let it be remembered that the x ray did not add a principle but an aid in the carrying out of the fundamental conception of treatment.

That our predecessors realized their limitations is adequately expressed by Cooper, Malgaigne, Hamilton, Gross, Lane, and a host of others. The x ray provided the opportunity for the surgeon to express himself either conservatively or radically. Conservatively, by the application of anatomical knowledge and physical principles, he could reduce a deformity definitely. When this was not accomplished he could safely apply direct exposure of the fracture site and make use of internal fixation for the purpose of assuring the reduction which was thus accomplished.

ing hospitals, it applies to all patient-physician relationships as well. One need only recount the remarks concerning blood pressure readings which may frighten and obsess the patient for days, or the chance remarks that the heart is enlarged, the splenic notch palpable, this or that being better or worse. Under all circumstances one should avoid the practice of ill-considered, tactless discussion of a patient's problems within his hearing. Even with children, lack of tact is fraught with danger, because children often understand spoken language more adequately than adults believe and are able to interpret and evaluate even the most subtle nuances of sign language.

The patient should be comforted, and placed at his ease, and if a foreigner, some attempt should be made to supply a nurse, attendant, or relative who speaks his language. By all means, the untactful use of charts, specimens, roentgenograms, and technical bedside discussions should be avoided. In this respect nurses and attendants should be trained to maintain a sympathetic and tactful attitude in the patient's presence. A simple and understandable formulation of the problem should be given to the patient. This explanation should include reasons for hospitalization, diagnosis, and purpose of operative intervention. These data may be given in such a way that they become reassuring rather than alarming. The introduction to the operating room should be done wisely, again untactful waits in the surgical anteroom with its usual forbidding atmosphere should be avoided.

Brief personality analysis. The practising surgeon encounters far too many psychiatric problems in his daily work to permit him to refer all of them to the specialist in mental disorders, nor is this necessary or desirable. We believe that a planned study of the personality factors involved in the various problems greatly enhances the likelihood of successful therapy. Everyone agrees that emotional, social, situational, and kindred factors may cause complications in any somatic illness, but without some systematic knowledge it is difficult to deal efficiently with the mass of facts accumulated by investigation. How, then, may the surgeon equip himself

with the information necessary to enable him to recognize, interpret, and treat the personality disorder that he may meet in his practice? Whether or not the patient is mentally ill before an operative procedure or may become so during or after such a procedure, is not as important as the interested attitude and factual groundwork of the surgeon. We believe that, if surgeons took the time and expended sufficient energy to investigate the past history of the patient, the relevant family data, the origin and development of present illness, the underlying personality of the patient and the signs and symptoms which may appear more or less to be related to the surgical complaint, there would be fewer unnecessary operations, and if intervention were indicated, the patient would be better prepared for it and would experience a much more tranquil convalescence. Incomplete examination and inadequate diagnostic study without evaluation of personality make-up may lead to unnecessary surgical intervention. Let the following case abstracts exemplify what is meant:

CASE 1 E. F., a white female, 27 years of age, single, was admitted to the medical outpatient department of the Colorado General Hospital on January 11, 1937, and was referred to the Psychiatric Liaison department on March 2, 1937. Her complaints were sudden, abrupt pains all over her body, puffing of various regions of the body, nervousness and depression of mood. Previous operative history was as follows: puncture of left ear drum at 9, tonsillectomy at 10, re-operation of tonsils at 13, nasal septum operation at 13, radium treatment for inward goiter at 13; appendectomy at 14, drainage of gall bladder at 22, puncture of cyst of right ovary at 22, cholecystectomy and right ovariectomy at 23, thyroidectomy at 25, hemorrhoidectomy at 26. Physical, neurological, laboratory and psychiatric examinations were completed and a diagnosis of a tense, depressed, insecure, hysterical personality with somatic conversion symptoms was established. Treatment was both supportive and causal with special care to point out the significance of the emotional factors of domestic incompatibility, worry over increasing age, unemployment and fear of invalidism. Inasmuch as it was necessary for the patient to return to her home in a distant part of the state, only 2 interviews were possible, during which time the patient was able to appreciate the rôle of the emotional factors in her present complaint.

CASE 2 The patient was a 21 year old, single, white girl, who entered the hospital with the family physician's statement: "Hyperthyroidism and ex-

THE PSYCHIATRIST IN RELATION TO SURGERY

FRANKLIN G EBAUGH, M D , Denver, Colorado

SURGEONS, both as technical operators and as physicians practicing the art of medicine, have often neglected an important phase of their science and art. They have failed to comprehend the *wholeness* of the personality and have been sidetracked into problems of cell or organ function. They have looked upon the sick person as an inert container of offending viscera and not as a reacting person with individual personality functions. Surgeons have failed to recognize that a patient is a unique collection of coordinated functions, an energy system in which every part while performing a special duty is, nevertheless, entwined with all the other functions, and that a change of function in one part is reflected in changes of functions in other parts and in the whole. It is the surgeon's job to remove or alter structures which are defective or diseased. His technical skill in accurate diagnosis and surgical interference is important, but he must know that his personality and the stage he provides may be more important.

What are the facts that will enable a surgeon to prevent or adequately care for the personality disorders which he meets in his work? How can he recognize these disorders if they are present? How can he avoid unnecessary surgery? How can he best prepare and care for the patient before, during, and after the operative procedure? Strangely enough, there is no need for any special equipment and no need for any complicated or cumbersome mechanical or electrical apparatus. The attitude and the facts necessary to deal competently with these problems are within the reach of anyone who wishes to have them and may be set forth as follows: (1) surgeon patient relationships, (2) time and patience necessary to allow the sick person to tell his story so that one can understand the nature of the individual, (3) appreciation of the fact that not all pain, tenderness, or dis-

ability is organic in nature, and that removal of whatever is associated with the pain will prove to be rational therapy, (4) avoidance of delirious or toxic states by means of judicious chemical sedatives or adequate hydration and nutrition in the postoperative, convalescent state. These are attitudes and facts that should be adopted and utilized.

Surgeon patient relationships Fact in physician patient relationships, sometimes called bedside manners, is a matter that is both endogenous and acquired. Unfortunately, in the development of bedside teaching in this country, students patterning their behavior on clinical instructors, even with the best intentions, do not deal with their patients in the most desirable way. Kahn and Powers considered the patients' emotional response to case discussion in a very lucid manner. Among other things they stated:

'The idea has been developing in medicine that physicians are not treating diseases but are dealing with diseased human beings. Doubtless some desirable progress has been made along this line and the fundamental idea seems to be well understood but in clinical pedagogy how is it possible to reconcile one's understanding of the patient as a human being with the teaching necessity of using him as material?'

In his preclinical years the student has been used to dealing with material of different kinds in a very free manner. He had the opportunity to discuss everything perfectly freely with his teacher individually or in a group regardless of the physical presence of the material concerned. When he comes into his clinical years he is confronted with a new situation. The connecting link between him and his teacher is no longer a guinea pig, an anatomical or pathological specimen or a biochemical reaction but another human being. The student is likely to throw himself on the patient with an eagerness similar to that which he displayed when taking hold of a preclinical 'material'. Even if it is as usual that a goodly number of students bring with them to their clinical years sympathetic understanding and much tact, the idea cannot be avoided that the development of their bedside manners will greatly depend on the 'bedside manners' of their clinical teachers.

While these remarks were devoted to a consideration of the patient as he is used in teach-

man will bear with equanimity a wen on his hand or a wart on his nose but a small varicosity in the scrotum will keep him awake at night and depress him during the day I have operated upon many varicoceles to cure a malady that was above the neck "

One should also mention the psychic trauma and concern over the frequent pelvic evisceration in the female and amputation of limbs in either sex. However, the most frequent complications are those encountered in the postoperative phase (2, 12). They may be due to the following: neglect in immediate postanesthetic care in respect to assurance, encouragement, and re-orientation, Preu and Guida recently described the *modus operandi* of postcataract panics, toxic and infectious complications leading to deliriums and other symptomatic psychoses, caused by the unwise choice of an anesthetic, etc.; lack of adequate fluid and nutritive factors causing dehydration, ketosis, avitaminosis, injudicious chemical sedation intensifying pre-existing delirious states or actually provoking drug delirium; and failure to inform the patient as to what was done and the result obtained.

The symptomatology of the complications varies in form and content. The following outline may be of value.

Pre-operative (1) Pre-existing instability, neurosis or psychosis intensified by hospital admission; (2) development of fear or panic state due to inadequate or injudicious preparation (ill-considered, tactless remarks, demonstrations, etc.)

Post-operative (1) Psychoneurotic symptomatology (from monosymptomatic hysterical syndromes to the more diffuse anxiety states), (2) symptomatic psychoses (deliriums due to chemical sedation or to toxins, infection, or malnutrition), (3) the frank psychoses (mania, various types of depression and schizophrenia).

Since drugs definitely increase the tendency to deliriums, a short discussion of the latter will be in place. A delirium may be defined as a disturbed mental state in which disorientation, a predominating effect of fear, and usually a tendency to hallucinations are present. These are closely connected with somatic conditions in that they are dependent upon, or associated with, intoxication, drugs or poi-

sons, nutritional disturbances, circulatory phenomena, and metabolic disorders. These disturbances produce temporary brain changes which are in the nature of edema, or the obscure concomitants of fever, dehydration, and acidosis. The occurrence of delirium should not be considered merely incidental to the principal disease picture. It is a complication that may, and in a great percentage of cases does, interfere with the treatment of the clinical problem in hand. To say the least, it increases the suffering, prolongs the duration of the illness, and may necessitate special hospitalization of the patient, it may even be a personality disorganizing factor of such magnitude as to produce chronic invalidism and incompetency. The delirious patient, befuddled, disoriented, hearing threatening voices, misinterpreting situations, overwhelmed by misgivings and fear and given to action, is in potential and acute danger of injuring himself and even of losing his life by jumping from a window. A very large percentage of deliriums either are preventable or can be ameliorated if recognized early.

TREATMENT

Treatment must, of necessity, be preventive as well as causal and supportive. The following points may be of value in stressing treatment possibilities.

1. It is most important to look upon the sick patient as a variously integrated personality rather than a caricature of a diseased viscus. This means that in addition to adequate physical, neurological, and laboratory examinations an attempt should be made to discover and interpret the development and significance of the symptomatology from the points of view of the personal and interpersonal aspects as well as the more tangible impersonal or somatic. This will include a careful differential diagnosis of those physical disorders which are frequently simulated or complicated by psychogenic factors, as thyrotoxicoses, gastric and duodenal ulcers, colitides, etc.

2. Simple, understandable and sympathetic formulations should be given to the patient. These should explain the nature of the immediate hospital environment, the nursing procedures, and the various examinations,

ophthalmic goiter for 12 years exophthalmos, fine tremor, enlarged thyroid, tachycardia. Examination disclosed an anxious, tense girl complaining of shortness of breath, pounding heart and choking sensation in the mid neck region. Her eyes were prominent with some exophthalmos, thyroid was not palpable, resting pulse rate was 84 and blood pressure 100/72. The patient had had an increased appetite but lost 5 pounds in 2 months and was sensitive to cold. The basal metabolism rate showed a minus 18 and minus 24. She had been referred to the hospital for psychiatric opinion by surgeons who rejected the diagnosis of toxic goiter. The patient came from a family in which the incidence of illness was high. She had never been able to carry through plans and responded to failure with temper tantrums and other symptoms. There were marked school difficulties at the age of 10 when she was told by her family doctor that she had a goiter. Her life since had been poorly organized and unproductive of needed satisfactions. With each failure the patient had fallen back on medical support and "goiter." The present illness appeared in a setting of disappointment incident to her being dropped from a beauty culture school after seriously burning a customer. With psychotherapy the patient developed insight was markedly improved and left the hospital to enter work consistent with her abilities.

CASE 3. A F 29 years of age was a white female married and the mother of a 4 year old child. She complained of constipation, a drawing sensation in the epigastrium, nausea, and marked belching after meals. Upon examination there was indefinite tenderness in the epigastrium without rigidity. The symptoms had come on 4 years previously. X-ray examination showed a duodenal deformity consistent with ulcer free hydrochloric acid 4 per cent total 11.5 occult blood 4 plus in stool. Laparotomy was performed and nothing was found. The study showed the patient to be a rather independent person who had always supported herself. Soon after her marriage she became pregnant and had to give up her job and depend upon her husband's smaller uncertain income. She resented this situation, became anxious about it and developed the above symptoms after the child which increased her responsibilities and accentuated the financial difficulties. When the diagnosis of ulcer was made the patient became body conscious and insecure and this has continued. Psychiatric study and therapy resulted in notable improvement.

These case histories are cited to stress the point that adequate investigation of the endowments and experiences of the personality will go far to prevent unnecessary surgical intervention. Not only will there be fewer unnecessary surgical operations, but fewer residual states of psychic or other invalidism in which the patient usually seeks an outlet for emotional conflict in the form

of bedfastness, an interminable series of operations, hypochondriacal concern over various system functions, and so on.

Psychosomatic relations. Much has been accomplished since Hawthorne remarked in the *Scarlet Letter*, "A bodily disease which we often think of as a thing apart and separate, may after all, be but a symptom of an illness in the spiritual part of our nature."

The recent reviews of Dunbar and Witt Lower have aided in drawing attention to some of the difficulties encountered in the study of psychosomatic relations. More specifically, the psychogenic aspects of thyrotoxicosis (1, 7a, b), and the disorders of the gastro intestinal tract (7b, 9a, b, 11), have been and continue to be sources of fruitful investigation. In the evaluation of the psychogenic factors 2 elements must be considered first, the underlying personality make up, and second, the exciting factor which may be in personal, personal, or interpersonal.

It is hoped that the recent introduction of psychiatry into the general hospital will serve as a means of teaching physicians and students the need for a more integrated approach to the sick person, as well as offering a fertile ground for further study of the psychogenic aspects of various clinical syndromes (5a).

Psychiatric complications in the postoperative phase. In previous communications (5b, c, d), the author has pointed out the most frequent psychiatric complications in surgery and in general practice. We have discussed the courtesy and tact of the surgeon in the pre-operative period. The rôle of the operation, itself, may be an important factor in precipitating or intensifying depressive or anxiety states.

Taylor, a surgeon, corroborated our impression that a disproportionate amount of emotion is aroused in any procedure which concerns the genital organs. Regarding genito-urinary surgery in the male he stated

Many changes may take place in the scrotum. Some of them are of little consequence, some may be disastrous. Not the least thing to be considered is the mental condition that often accompanies any pathological condition affecting the genitals. It is often found necessary to correct some trifling disorder that otherwise would be ignored, to cure a neurasthenia that is wrecking a business career. A

THE TREATMENT OF OTITIC MENINGITIS DUE TO STREPTOCOCCIC INFECTION BY SURGERY AND SULFANILAMIDE

CARL H McCASKEY, M D , F A C S , Indianapolis, Indiana

ALMOST unbelievable is the improved prognosis in streptococcic meningitis brought about by the introduction of sulfanilamide and its derivatives. Scarcely 3 years ago G Domagk first reported this valuable form of chemotherapy, and yet the numerous enthusiastic reports in the literature already indicate a vastly improved future for streptococcic meningitis therapy (3, 16, 23, 33, 35, 41). Our pre-sulfanilamide records, as well as those of others, show a depressing mortality of close to 100 per cent for streptococcic meningitis, the type or the earnestness of treatment notwithstanding; whereas the previously mentioned articles indicate an encouraging 20 to 45 per cent mortality. The cases to be reported here, also, substantiate this more hopeful outlook.

The term otitic meningitis implies, of course, a meningitis resulting from a pathological auditory apparatus. Its significance to the otolaryngologist is best shown by a series of autopsies including 110 cases of suppurative meningitis in which approximately three-fourths were shown to have otitic infection as the primary etiological factor (11). To establish such a diagnosis clinically one must rule out by careful history and physical examination (1) any infectious process, local or general, producing the meningitis and antedating the otitis media, or (2) any intercurrent infection which is accompanying a suppurative otitis but which in itself accounts for the meningitis. Not infrequently an ear infection, throwing out organisms to produce a meningitis, is overlooked or more often considered non-surgical because of a lack of clinical or x-ray findings. The practising physician must

learn the lesson vividly portrayed in recent years at the Indiana University Hospitals by 5 streptococcic meningitic autopsies, 3 of which disclosed unoperated upon unilateral or bilateral mastoiditis and otitis accounting for the meningitis.

Our desire is to describe 7 cases of meningitis treated with sulfanilamide and surgery as indicated. Four had hemolytic streptococcic meningitis, 1 a serous meningitis accompanying an acute streptococcic otitis and mastoiditis, 1 a serous meningitis with a Gram positive bacillary otitis and mastoiditis, and 1 a meningitis due to an unknown Gram negative bacillus. It seems warranted first to emphasize briefly salient points concerning streptococcic otitic meningitis and the chemotherapeutic agent, sulfanilamide.

ETIOLOGY AND PATHOGENESIS OF STREPTOCOCCIC OTITIS MENINGITIS

Obviously by definition such a meningitis results from the entrance of streptococci into the cerebrospinal system from an otitic focus. Such a meningitis tends to be fulminating; however, the actual speed of development depends largely upon the pathway of infection (8).

Pathogenetically, the organisms may travel from the ear to the meninges by direct extension via the eighth nerve, through persisting sutures or dehiscences, through the aqueductus cochleæ or ductus endolymphaticus (27), or through an osseous discontinuity resulting from trauma or operative procedure. The spread may be hematogenous, but probably most common is the propagation by thrombophlebitis from an area of osteomyelitis or periostitis produced by an expanding middle ear infection (10). A true streptococcic meningitis will be suppurative in type although one may have a serous or sympha-

From the Surgical Department of Indiana University School of Medicine through the Otolaryngological Division.
Presented before the Clinical Congress of the American College of Surgeons, New York, October 17-21, 1938.

3 One should avoid untactful remarks, unnecessary phrases or the demonstration of charts and roentgenograms which may startle or frighten the patient

4 One should take care to avoid overdosage of chemical sedatives, to be aware of susceptibility to the various drugs used in basal anesthesia, and to use hydrotherapy whenever possible

5 Toxic and infectious complications should be prevented by due attention to fluid balance and to an adequate nutritive state

6 In unstable individuals, particularly in the psychoneurotic group, operative intervention, in all but emergency conditions, should be postponed. It is in this group of problems that one meets the all too frequent operation for the removal of adhesions. A careful scrutiny of the presenting complaint from all points of view, including that of a brief personality appraisal, will decrease the number of unnecessary operative procedures

7 If operative intervention is indicated in a patient who is manifestly neurotic or psychotic, psychotherapeutic measures should be instituted, if possible, before and after the operation

SUMMARY AND CONCLUSION

The attention of the surgeon has been called to the following needs: tact in surgeon-patient relationship, thorough and adequate personality analysis of each patient, appreciation of the rôle that emotional conflicts play in creating, complicating, or masking somatic disease, and the avoidance of postoperative complications by the maintenance of an adequate fluid balance, nutritive state and the judicious prescription of chemical sedation

This has been a most welcome opportunity to review a few major problems which need the mutual co-operation of the psychiatrist

and the surgeon. Each is a practitioner of the healing art upon the patient, who should not be thought of as a mechanized collection of organs, but as a reacting person with individual personality functions. It is hoped that a wider dissemination of this point of view will lead to greater understanding and to further perfection of methods of diagnosis and treatment in the field of our common interests

surgery rather than as a substitute for localized drainage. Philosophically, Lewy states, "The elimination of a large amount of surgery now done in otogenic meningitis may be in the offing, but it would still seem advisable to operate until our diagnostic skill is improved, particularly so with chronic ears."

Exposure of the dura to the full extent of involvement has become a widely used procedure, advocated by many. Some (14), on the other hand, are not convinced of its efficacy, and almost all are opposed to opening the dura unless definitely indicated. In such a case it is wise to close over the dural gap with fascia, muscle, or some other tissue so as to avoid a persistent connection with the pneumatized air cells which might serve as a pathway for future infection.

For cerebrospinal fluid drainage the tendency is toward simple, regular lumbar punctures at 8 to 24 hour intervals depending on the amount of intraspinal pressure and cisternal or ventricular taps in the event of block. Lumbar puncture was first introduced in 1890 by Wynter, and cisternal drainage in the following year by Ballance (18). Procedures described since that time have tended to be more radical, a recent example of which is Kubie's method of forced drainage. These more formidable procedures are frowned upon to a great degree (18, 23, 35).

Supportive care plays a major rôle in every streptococcic meningitis recovery. The usual severity of such a case demands intravenous fluids and frequent transfusions according to the indications as well as absolute physical and mental rest. Sedation permits calmness and conservation of energy, an easily assimilative and eatable diet plus ample fluids allow build-up and support. Stimulants of general metabolism and hematopoiesis, particularly leucocytosis, can be of value. Atkinson stresses these points in his pre-operative management of acute streptococcic mastoiditis, but unfortunately with otitic meningitis one cannot wait for mastoid localization, as he advises in treating mastoiditis *per se*, since most of the value derived from surgery is obtained early in surgery.

Fighting the infection by means of serums and chemotherapeutic drugs has made the

greatest recent advancement because of sulfanilamide's introduction. The many types of serum offered on the market are of variable value in therapy. Autogenous serum intraspinally has been recommended highly by some (27), particularly in a slowly responding case. They reason that the blood has attained a fairly high titer by that time, and since the choroid plexus tends to prevent the passage of immune bodies, intrathecal administration of the blood serum should raise the titer in the cerebrospinal fluid.

The therapeutics of sulfanilamide have received bountiful attention subsequently to its advent into medical literature. It probably has shone most brightly in the treatment of streptococcic meningitis. Recommended dosage varies to a moderate degree, but a review of the vast number of reported cases in the literature suggests a considerable amount of agreement among clinicians. Oral and rectal administrations of sulfanilamide are preferred although an 0.8 per cent sulfanilamide solution given subcutaneously and intramuscularly, or subcutaneous prontosil injections, are noteworthy in the vomiting or comatose patient. Intravenous sulfanilamide usage is advised by only a few men and intrathecal administration of the drug is discouraged by Adolph and Lockwood, and others (3 et al.) who reason, that because the streptococci are doing their damage deep in the meninges rather than out in the cerebrospinal fluid, sulfanilamide placed therein can have little effect. Furthermore, the spinal fluid concentration of sulfanilamide approximates closely that of the blood despite the method of administration.

Dosage has more or less regulated itself to around three-fourths of a grain of sulfanilamide per pound of body weight taken orally at 4 to 6 hour intervals, 5 to 50 cubic centimeters of 0.8 per cent sulfanilamide solution or prontosil parenterally at 6 hour intervals or longer depending on the case. Simultaneous dosage of sodium bicarbonate orally or sodium lactate intravenously, if the patient is unable to take alkali by mouth, will combat the acidotic tendency which often develops. We and many others (3, 5, 35) have noted the rapidity with which a patient with impaired renal function will build up a blood sulfanilamide concentra-

thetic meningitis with turbid spinal fluid under increased pressure, increased cell count (usually predominantly polymorphonuclears), and negative albumin, globulin, smear, and culture. A localized suppurative meningitis with an accompanying serous meningitis is also possible.

DIAGNOSIS

The history and the physical findings of meningeal irritation plus the laboratory report of the prompt diagnostic spinal tap usually lead to a diagnosis. One must bear in mind and differentiate by the above procedures other possibilities such as meningismus which usually accompanies acute systemic infections, encephalitis, poliomyelitis, and benign lymphocytic choromeningitis, acute syphilitic meningitis, subarachnoid hemorrhage, localized suppurative meningitis, and serous meningitis (46). The latter 2 conditions and a generalized suppurative meningitis tend to come into the hands of otolaryngologists because etiologically there is often an underlying otitis, mastoiditis with associated epidural abscess, or sinus thrombosis.

The spinal fluid in streptococcal meningitis is characteristically turbid under increased pressure, elevated cell count, and polymorphonuclears predominating as a rule. The cloudiness is produced by the resultant irritative tissue exudation (10) thereby serving partly as a guide to the case's progress. The albumin, globulin and lactic acid are variably increased. A typical meningitic gold curve will usually be obtained. Serology, smear, and culture are valuable in differentiation, and the streptococci will eventually be found thus if they have broken out of the original focus in sufficient number and it permitted to multiply. Degenerative forms of streptococci and certain other pathogenic organisms may appear Gram negative.

Other laboratory work such as urinalysis, blood count, and the like must be considered in evaluating a case. To follow a patient's progress adequately one can follow the suggestions of Maxwell in the management of otitic sepsis. He advises observing frequent pulse, respiration, and temperature readings, following daily blood counts, urinalyses with centrifugate smear study, and blood cultures,

examining the patient often, and ordering chest x ray examination, etc., when indicated. The good clinician never forgets that the sick patient, as one with meningitis for example, may contract some other pathology to complicate the picture.

Streptococcal meningitis calls for prompt diagnosis and treatment. One must not delay in performing a diagnostic spinal tap carrying through any surgical procedure that is indicated, and instituting other therapeutic measures. A few hours of procrastination may greatly affect the prognosis. Persistent headache and developing meningeal irritation in the presence of otitis and mastoiditis calls for immediate action particularly so with a sclerotic or poorly pneumatized mastoid in which the easiest pathway for the infection is toward the meninges.

TREATMENT

Therapy in streptococcal meningitis, as noted, demands prompt, logical action. Here, as in numerous phases of medicine, one finds a wide variation in the recommendations proposed by different successful clinicians. An article late in 1937 (27) reviewed extensively the multitude of therapeutic procedures which have had their day or are now in vogue. Nevertheless most of the recent literature indicates that the majority subscribe mainly to the fundamental objectives of (1) elucidating the etiological focus, (2) draining the cerebrospinal fluid regularly and frequently, (3) neutralizing infection with serums and chemotherapeutic agents, and (4) supporting the patient conscientiously.

Removal of the primary focus usually calls for surgery, which must be adequately complete for each particular case. Whether one does (1) a simple mastoidectomy, (2) a radical mastoidectomy, (3) an uncovering or opening of the lateral sinus, (4) a wide exposure of the dura, (5) a labyrinthotomy, or (6) a revision of the entire operative field when the meningitis follows surgery, depends upon the case history, examination, and findings at operation. The introduction of sulfanilamide has been hailed by some as a possible substitute for surgery in these cases. Far more logically, sulfanilamide should serve as an adjunct to

of sulfanilamide than does the blood due to a concentrating power of the mammary gland; and (3), the drug, when given to a pregnant woman, reaches the placenta and may account for increased fetal mortality and morbidity.

DERIVATIVES OF SULFANILAMIDE

Although vast numbers of sulfanilamide derivatives have been tried experimentally and clinically, the original product appears far ahead at present in effectiveness and applicability. The derivative running a close second is prontosil and its concomitant usage with sulfanilamide receives considerable comment in the literature. Neoprontosil has been found to be apparently less toxic clinically and a worthy substitute for sulfanilamide although absorbed more slowly (5). The same clinical series found di-methyl-di-sulfanilamide less toxic in general usage except for a peripheral neuritis developing in approximately 6 per cent of the cases. This drug was, therefore, not used further. Neoprontosil yields only one-fourth its weight in sulfanilamide so that Applebaum feels that its therapeutic action results from some other factor besides sulfanilamide. He recommends its use orally as well as a combination therapy with the less complex sulfanilamide.

Enumeration of further instances of satisfactory sulfanilamide therapy as reported in the literature includes cases of erysipelas, pneumonia, scarlet fever, streptococcal sore throat, adenitis, urinary infections, sinusitis, and many others (17 et al.). Of almost unquestionable value is its administration in streptococcal otitis media and mastoiditis, particularly in the prevention of complications therein (2).

On the other hand an attempt to clear up several cases of positive streptococcal throat carriers proved disappointing (21). A still more varied application of the drug is found in the recent reported satisfactory treatment of ulcerative colitis with neoprontosil (5). No doubt, in final analysis, such ardent widespread application of the drug will be unwarranted but at present no one can be criticized for trying it in certain conditions, particularly those for which past therapy has proved discouraging.

TOXICITY OF SULFANILAMIDE AND ITS DERIVATIVES

Medical history relates again and again the consequential disasters which almost invariably follow the introduction and extensive application of a drug greeted with such enthusiasm as was sulfanilamide. Complications therewith obtained a head start through the unfortunate "elixir of sulfanilamide," which later was proved to have brought about so many fatalities because of its solvent, diethylene glycol (15). No doubt, to prevent such mishaps any future therapeutic agent should receive exhaustive experimental tests for toxicity, compatibilities, and the like, prior to its acceptance by the medical profession; and yet, experimentation progresses cautiously and painstakingly, whereas enthusiastic therapy too often runs hog wild.

Even though the drug has many toxic manifestations, fortunately most of them are not serious, regrettably, the mechanisms producing many of them are not known. Experimentally, with mice, rabbits, dogs, and human marrow cultures, no permanent tissue damage could be demonstrated after an average dose (31, 36). Possible toxic manifestations are, namely, malaise, anorexia, nausea, vomiting, tinnitus, dizziness, mental confusion, cyanosis, fever, abdominal cramps, diarrhea, hepatitis, nitrogen retention dermatitis, anemia, thrombocytopenia, and perhaps others. The "drug fever" usually appears after a week to a week and a half of therapy. As to the incidence of these, it is impossible to formulate any complete statistics, however, in a series of 114 consecutive cases of beta-hemolytic streptococcal infections treated with sulfanilamide by Hageman and Blake (17) such toxic complications occurred in 56 per cent, with cyanosis being by far the most common. Whether some of these in the future can be prevented in a similar manner, as is acidosis with its resultant cyanosis now avoided by the concomitant administration of alkali, rests with future experimentation. Some acetyl sulfanilamide is produced from absorbed sulfanilamide, and data indicate that it is more toxic than sulfanilamide itself (31).

The toxic reactions enumerated are soon relieved almost invariably by discontinuing

tion This factor plus the several toxic manifestations customary with this drug group must always be borne in mind regardless of the dosage being used

Sulfanilamide has been proved to be of value in treating experimentally induced streptococcal meningitis in white rats (2), rabbits, and monkeys (25) Other recovered cases of otitic streptococcal meningitis treated clinically with sulfanilamide and mastoidectomy as indicated are cited in the recent literature by authors other than those mentioned (13, 17, 38, 42, 44, 45) Among numerous other articles are complete recoveries reported for a case of otogenic meningitis due to an anaerobic Streptococcus haemolyticus beta (43) and a case due to a non hemolytic streptococcus (30) Experimentally in monkeys and rabbits (25) and clinically it appears encouraging in pneumococcal meningitis when used conjointly with specific type serum (3, 35), and may prove helpful in the future in treating meningococcal and influenzal meningitis The drug's great success in otogenic meningitis may warrant its usage in the future as an empirical treatment, despite negative spinal fluid cultures (26)

PHARMACOLOGY OF SULFANILAMIDE AND ITS DERIVATIVES

Of chief interest is the mode of action of sulfanilamide about which there has appeared much ado in recent literature Long and Bliss (28), American pioneers in this momentous therapeutic advancement first described the effectiveness of the drug as being due to bacteriostasis which in turn promoted phagocytosis by the polymorphonuclear cells early in treatment and by the monocytes later Further experimentation by these workers (29) strengthened their original conclusions and promoted the theory that retarded streptococcal proliferation lessened the output of leucocidins and similar toxic products, thereby aiding phagocytosis

Based upon widely varied clinical and experimental observations, other men (22, 25) have arrived at conclusions basically similar to those of Long and Bliss However, some have maintained that the primary effect is a neutralization of the organismal toxins, the

aggressins, leucocidins, and other antiphagocytic substances (36, 37) To improve the tenability of this viewpoint Osgood and Brownlee (36) remarked "Clinically the sulfanilamide's rapid alteration of the course of erysipelas, streptococcal meningitis, etc., is more easily explained on the basis of neutralization of toxin than on the basis of a bactericidal action" Contradictorily, others (20) disclaim any antitoxic mode of action but instead stress the slowing effect on streptococcal multiplication and metabolism which in turn accounts for decreased toxin formation Still others (2, 45) have published their experimental work disproving the theory that increased phagocytosis plays a part in sulfanilamide action Working with white rats and mice they could show no evidence of increased phagocytosis by either the leucocytes or cells of the reticulo endothelial system Clinical observation indicates that the effect of the sulfanilamide apparently is independent of the leucocytes since a developing leucopenia is the rule and there occurs no proportionate increase in the polymorphonuclear cells (7) Hedging on the issue, we are inclined to believe that sulfanilamide furthers bacteriostatic, bactericidal and antitoxic action, thus reinforcing the body's own mechanisms to eradicate certain types of infection

As to sulfanilamide's effective concentration the use of human marrow cultures showed a 1:100,000 concentration to be as efficient as any against the streptococcus (36) Now, such a proportion is easily obtained by the accepted administration of sulfanilamide and can be maintained by doses at approximately 6 hour intervals, because in the average case the maximum blood concentration is reached in 4 to 6 hours Within recommended dosage the blood sulfanilamide percentage will be roughly proportional to the amount of drug given provided no impaired urinary excretion exists, as noted Hepatic damage or moderately severe anemia likewise warrants extra precautions to prevent dangerous concentrations Noteworthy, also, are a few observations concerning excretion (1) (1) Sixty to 70 per cent of absorbed sulfanilamide leaves via the urinary tract, (2) in the lactating mother the milk carries a higher concentration

Fig 2 Case 2 An acute hemolytic streptococcic meningitis, mastoiditis, and otitis media complicating scarlet fever

Symptoms grew progressively worse. The past history was negative except for frequent bilateral suppurative otitis. Examination on admittance showed the patient to be acutely ill and irrational, with right ear drainage, right mastoid tenderness, infected tonsillar crypts, dental sordes, neck rigidity, and absent patellar reflexes. On the day of admittance a right mastoidectomy was performed. Pus was found together with extensive bone necrosis. The dural plate of the middle fossa was involved, and a wide exposure of the dura as well as of the lateral sinus was performed. Sulfanilamide was administered rectally and later orally. Frequent spinal fluid drainage was performed and general supportive measures used. The patient had a good recovery and was discharged on July 18, 1938. The laboratory findings were as follows: white blood count on admittance 19,400, red blood count 3,800,000, urine negative except for few hyaline casts and pus cells; spinal fluid cell count 2,290 with elevated globulin and lowered sugar, 3 positive hemolytic streptococcus cultures, x-ray of right mastoid showed increased density and sclerosis. The final diagnosis showed (1) mastoiditis and otitis media, acute right Streptococcus hemolyticus, and (2) meningitis, Streptococcus hemolyticus.

CASE 2 No 22001, J F, male, white, aged 8 years. The patient, an emergency case, was brought to Riley Hospital on March 3, 1938, with headache, draining right ear, backache, and occasional vomiting. The onset had occurred 23 days before with bilateral earache, 2 days later scarlet fever rash was noted, and bilateral aural drainage started 3 days

afterward. Sulfanilamide was administered by a local doctor. After 1½ weeks frequent headaches occurred. This and other symptoms were severe for the last 2 days before admission. Two years previously both ears had been draining. Examination on admittance showed a desquamating skin, purulent right otitis, and right mastoid tenderness.

Fig 3 Case 3 An acute hemolytic streptococcic meningitis following a unilateral mastoiditis and terminally developing a suppurative labyrinthitis

Fig 1 Case 1 A hemolytic streptococcal meningitis resulting from an acute hemolytic streptococcal otitis media and mastoiditis

the sulfanilamide Graver complications, which appear more like drug idiosyncrasies, happen all too frequently for comfort, judging from the numerous reports in the literature. Six or more cases of fatal granulocytopenia have been reported due to sulfanilamide or prontosil, these reports demonstrated maturation arrest in the bone marrow and phagocytosis of iron pigment, representing a hemolytic type of anemia (6, 40). At the Indiana University Hospitals we have experienced only one such case which ended miraculously in recovery.

Another serious complication, acute hemolytic anemia occurs occasionally and, like most drug idiosyncrasies, develops as a rule with surprising rapidity. Judging from the several cases cited in the literature (10, 24), one can expect satisfactory recovery after withdrawal of the drug and one or more transfusions. Much more commonly a patient develops a maculopapular dermatitis 1 to 3 weeks after the first dose of sulfanilamide which clears with some desquamation over a period of days to weeks after the drug is discontinued. Other toxic symptoms tend to precede the skin rash so that this toxic manifestation can frequently be prevented by reducing the dosage, or, if possible by stopping the drug's administration. Severe cases of dermatitis medicamentosa from sulfanilamide

have been described during the past year (12, 34, 39).

This discussion concerning sulfanilamide toxicity emphasizes the necessity for continued observation of the patient in order to note the appearance of any early toxic manifestations. The latter should serve as danger signs to promote a closer check on the patient's general condition, hemoglobin readings and blood counts. Beware of a developing leucopenia or anemia!

PRESENTATION OF CASES

The accompanying tables represent in the upper graph the patient's temperature course, the day when surgery and transfusions were performed, and the daily sulfanilamide dosage. The lower graph in each table shows the spinal fluid cell count, the spinal fluid sugar, and the blood or spinal fluid sulfanilamide concentration in milligrams per 100 cubic centimeters of blood.

Four cases of proved hemolytic streptococcal meningitis were treated with mastoid surgery as indicated and sulfanilamide.

CASE 1 No 20506 L. McC., male white, aged 6 years. The patient an emergency case was brought to the Indianapolis City Hospital on June 15, 1938 with right auricular pain and drainage, high temperature and irritability. Earache had begun 4 days before and spontaneous drainage the next day.

Fig 2 Case 2 An acute hemolytic streptococcal meningitis, mastoiditis, and otitis media complicating scarlet fever

Symptoms grew progressively worse. The past history was negative except for frequent bilateral suppurative otitis. Examination on admittance showed the patient to be acutely ill and irrational, with right ear drainage, right mastoid tenderness, infected tonsillar crypts, dental sordes, neck rigidity, and absent patellar reflexes. On the day of admittance a right mastoidectomy was performed. Pus was found together with extensive bone necrosis. The dural plate of the middle fossa was involved, and a wide exposure of the dura as well as of the lateral sinus was performed. Sulfanilamide was administered rectally and later orally. Frequent spinal fluid drainage was performed and general supportive measures used. The patient had a good recovery and was discharged on July 18, 1938. The laboratory findings were as follows: white blood count on admittance 19,400, red blood count 3,800,000, urine negative except for few hyaline casts and pus cells, spinal fluid cell count 2,290 with elevated globulin and lowered sugar, 3 positive hemolytic streptococcus cultures, x-ray of right mastoid showed increased density and sclerosis. The final diagnosis showed (1) mastoiditis and otitis media, acute right *Streptococcus hemolyticus*, and (2) meningitis, *Streptococcus hemolyticus*.

CASE 2 No 22001, J F, male, white, aged 8 years. The patient, an emergency case, was brought to Riley Hospital on March 3, 1938, with headache, draining right ear, backache, and occasional vomiting. The onset had occurred 23 days before with bilateral earache, 2 days later scarlet fever rash was noted, and bilateral aural drainage started 3 days

afterward. Sulfanilamide was administered by a local doctor. After 1½ weeks frequent headaches occurred. This and other symptoms were severe for the last 2 days before admission. Two years previously both ears had been draining. Examination on admittance showed a desquamating skin, purulent right otitis, and right mastoid tenderness.

Fig 3 Case 3 An acute hemolytic streptococcal meningitis following a unilateral mastoiditis and terminally developing a suppurative labyrinthitis

Fig 4 Case 4 An acute unilateral hemolytic streptococcal mastoiditis with a superimposed hemolytic streptococcal meningitis

There were positive neck leg and contralateral leg signs. A prompt right mastoidectomy was performed but no evidence of dural perforation was found. The lateral sinus was exposed and the wound drained and closed. Thirty five grains of sulfanilamide was administered orally for 8 days. 45 grains 4 times daily and then tapered off dosage during next 6 days. Eight tenths per cent sulfanilamide solution was administered intrathecally 12 times 3 to 4 grains each time. There were also 4 transfusions frequent fluid drainage and other supportive measures used. The patient had an uneventful convalescence and was discharged with healed wound and dry ear on March 15 1938. Laboratory tests showed urinary casts and pus cells at first, white blood count 14 600 to 20 300 to normal, spinal fluid count 800 sugar too low to read elevated globulin and protein meningitic gold curve, 7 positive cultures and smears for Streptococcus hemolyticus and the right mastoid hazy on x ray. The final diagnosis revealed (1) mastoiditis and otitis media, acute hemolytic streptococcus, (2) meningitis, hemolytic streptococcus and (3) scarlet fever convalescent.

CASE 3 No 22367, J D D male, white aged 12 years. This patient was an emergency admission to Riley Hospital on April 27 1938. He had frontal headache draining right ear and was irrational two and one half weeks before he had had tonsillitis and a week later suffered with headache and earache. Two days later a local doctor removed a bean from

the right ear canal. There had been bloody and purulent drainage since. Four days after the patient showed meningitic signs and had been irrational for the 4 hours previous to admission. Examination on admittance showed a thick purulent drainage from the right ear, and the patient was stuporous. There were positive neck and leg signs. Babinski was positive on the left, but there were absent patellar and Achilles reflexes. On the first day a simple right mastoidectomy was performed at which time pus and a tense infected dura were found. Sulfanilamide was given orally from the second day on. The entire repeated spinal tap with 0.8 per cent sulfanilamide solution intrathecally 9 times giving about 5 grains each time. Blood transfusions intravenous fluids, anti streptococcus serum etc were given but the course was steadily downward nasal oxygen being used during the last 2 days. The patient died on May 9 1938. No autopsy was performed but an examination of the mastoidectomy was permitted. A subluxation of stapes and a suppurative labyrinthitis were found. The laboratory findings were as follows: white blood count 18 800 to 37,800 to 31 600 hemoglobin 13 to 9.5 red blood count 4 370 000 to 3 330 000 urine contained albumin spinal fluid count 7 600 to 9 810 to 5 600 with a high polymorphonuclear percentage increased globulin and protein no sugar meningitic gold curve. Cultures and smears were positive persistently for Streptococcus hemolyticus. Highest blood sulfanilamide

Fig 5 Case 5 A serous meningitis accompanying an acute unilateral streptococcal otitis and mastoiditis, complicated by a petrositis of the same side and bilateral bronchopneumonia

percentage was 8.8 milligrams. The final diagnosis revealed (1) acute mastoiditis, right *Streptococcus hemolyticus*, (2) meningitis, *Streptococcus hemolyticus*, and (3) right, suppurative labyrinthitis.

CASE 4 No 22334, R D, male, white, aged 5 years. This was an emergency case brought to the Riley Hospital on April 20, 1938. The patient had a pain in neck, headache, and leg ache which developed during the 3 days previous to admission. There had been right ear drainage for 10 days, and urinary frequency was noted during the last 24 hours. Examination showed right ear draining, left drum white and bulging, patchy exudate on large tonsils, marked adenopathy on the right, and typical meningitic symptoms. A left myringotomy and right simple mastoidectomy were performed immediately. Necrotic bone, overlying the lateral sinus, and a tense and injected dura were found. The patient was started on oral sulfanilamide and given transfusions, supportive treatment, intravenous fluids, etc. Repeated lumbar punctures were done as the patient gradually improved. Two months later he required a left simple mastoidectomy. The patient received 4 x-ray treatments to mastoids and improved. He was discharged July 26, 1938. Laboratory findings were as follows: white blood count 22,500 with 82 per cent of polymorphonuclears on admission, non-protein nitrogen .48, spinal fluid cell count 1800 with high polymorphonuclear percentage to 1,976 to normal, increased globulin and protein at first, positive cultures of spinal fluid, blood, and ear for *Streptococcus hemolyticus*. The highest blood sul-

fanilamide percentage was 90 milligrams, blood counts became normal except for a mild secondary anemia, pus cells and casts in urine cleared. The final diagnosis revealed (1) mastoiditis, acute, right *Streptococcus hemolyticus*, (2) meningitis, *Streptococcus hemolyticus*, and (3) mastoiditis on the left.

Two patients with serous meningitis, resulting from an acute unilateral otitis and mastoiditis, recovered with surgery as indicated, sulfanilamide, and general supportive measures. Etiologically the otitic infection in one was due to the streptococcus, and in the other to a Gram positive bacillus.

CASE 5 No 22116, B C, female, white, aged 7 years. The patient, an emergency case, was admitted to Riley Hospital on March 16, 1938, with headache, vomiting, fever, neck rigidity, and coma. The onset occurred 9 days previously with headache and right earache. Nausea and vomiting followed the next day and 2 days later irritability and neck rigidity were noted. Two days after the right drum drained spontaneously and irrationality and coma developed. Examination on admittance showed the patient to be acutely ill, cyanotic, comatose, with right lateral rectal weakness, bulging right drum, positive Kernig's, Babinski bilateral positive, and evidence of bilateral bronchopneumonia. The patient was placed in the oxygen room. After 2 transfusions and other supportive measures a right simple mastoidec-

Fig 6 Case 6 A serous meningitis with an acute unilateral mastoiditis and otitis media due to a Gram positive bacillus

tomy was performed under local anesthesia on the third day. There was very little bony destruction and the lateral sinus and dura were not exposed. Oral sulfanilamide was given and the patient improved and was returned to the ward after 4 days. There were repeated spinal taps and 2 additional transfusions were given. However because of redeveloping sepsis a revision of the mastoidectomy was done on April 4, 1938. A suspected petrositis was found and the dura was exposed over the middle fossa. There was a slow but good recovery and the patient was discharged on May 15, 1938. Laboratory findings were as follows: white blood count 18,600 to 26,200 to 7,600; hemoglobin 9 to 11; spinal fluid count 1,213 with high polymorphonuclear percentage to 2,016 to 45; sugar low; elevated globulin and protein; ear cultures were found positive for streptococcus; blood and spinal fluid cultures were negative. The final diagnosis revealed (1) otitis and mastoiditis; acute right streptococcus; (2) serous meningitis; (3) right petrositis; and (4) bilateral bronchopneumonia.

CASE 6 R B male white aged 10 years. This case was an emergency admission to Riley Hospital on February 21, 1938. The patient had headache, nausea and vomiting, pain in right ear and stiff neck. The onset occurred 2½ weeks before with sore throat followed by earache. He improved until 1 week previous to admission when the symptoms mentioned began. His past history was essentially negative. Examination on admittance showed a bulging right drum, bilateral papilledema, positive Brudzinski, Babinski and Kernig. A local doctor had given the patient sulfanilamide. A right mas-

toidectomy had been performed at once exposing the dura over the middle fossa. The sinus plate was soft. A good recovery followed with sulfanilamide 30 grains being administered daily for 8 days, 20 grains daily for 6 days, blood transfusions, frequent spinal fluid drainage and supportive measures. The patient was discharged on March 15, 1938, with the wound healed. Laboratory findings were as follows: blood sulfanilamide on admission 11 milligrams; white blood count 7,950 to 15,600 to 7,300; spinal fluid count 2,765 to 36; spinal fluid culture was negative; sugar was too low to read to normal; ear culture showed Gram positive bacillus. The final diagnosis revealed (1) acute right mastoiditis; (2) right otitis media; Gram positive bacillus; and (3) serous meningitis.

One case with acute unilateral, hemolytic streptococcal otitis and mastoiditis and an accompanying meningitis due to an unknown Gram negative bacillus was treated successfully by mastoid surgery and sulfanilamide.

CASE 7 No 21979 E H male white, aged 13 years. This patient an emergency case was admitted to Riley Hospital on February 26, 1938, with severe right earache, fever and weakness. The onset occurred 8 days before but there was no aural drainage. During the year previous he had had 3 attacks of right otitis media. Examination on admission showed a bulging right ear drum, red and tender right mastoid, positive Kernig, Babinski and Brudzinski, and temperature up to 104 degrees. On the following day a radical right mastoidectomy

Fig 7 Case 7 Acute unilateral hemolytic streptococcal otitis and mastoiditis, occurring with a meningitis due to an unknown Gram negative bacillus

was performed when large cholesteatoma, extradural abscess, and massive granulations about the lateral sinus were found. The dura was widely exposed and the wound left open. The patient was given 60 grains of sulfanilamide daily for 7 days, then 40 grains daily for 12 days, and 20 grains daily for 7 days. A total of 1040 grains was given in all. Blood transfusions were given and frequent spinal fluid drainage was done. A good recovery followed and the patient was discharged April 13, 1938. Laboratory findings showed white blood count 13,000, 92 per cent polymorphonuclears, spinal fluid count 8,000, ear culture positive for *Streptococcus hemolyticus*, spinal fluid cultures revealed an unknown Gram negative bacillus, highest blood sulfanilamide concentration 4.4 milligrams. The final diagnosis revealed (1) mastoiditis and otitis media, acute right *Streptococcus hemolyticus*, and (2) meningitis, Gram negative bacillus.¹

SUMMARY

Pre-sulfanilamide records of streptococcal meningitis show a depressing mortality of almost 100 per cent, whereas recent reports and our results indicate an encouraging 20 to 45 per cent.

Approximately three-fourths of all suppurative meningitis cases are caused by a pathological auditory apparatus. The importance of this pathogenetic factor cannot be overemphasized.

The etiology and pathogenesis of streptococcal otitis meningitis are discussed briefly.

Diagnosis must be prompt. One must not delay in performing a diagnostic spinal tap, carrying through any surgical procedure that is indicated, and instituting other therapeutic measures.

Treatment of streptococcal otitic meningitis consists essentially of the following factors: (1) eradication of the etiological focus by

¹According to Dr. Edith Haynes, bacteriologist of Indiana University Hospitals, this organism, "a small Gram negative bacillus obtained in culture from nine specimens of spinal fluid was non-motile. It produced acid and gas from dextrose and galactose, and slowly acidified glycerol but fermented none of fourteen other carbohydrates and alcohols tested. It did not liquefy gelatin and produced no change in milk. It formed indol and reduced nitrates to nitrites. We were unable to classify it. It is possible that it was a saprophyte."

surgery which is adequately complete for each particular case, (2) drainage of the cerebrospinal fluid must be regular and frequent the simpler procedures preferable, (3) support the patient conscientiously with transfusions, intravenous fluids, physical, and mental rest, etc., (4) fight the infection with serums and above all sulfanilamide

Sulfanilamide's action may be stated as furthering bacteriostatic, bactericidal, and antitoxic action, thus reinforcing the body's own mechanisms to eradicate certain types of infection

Neoprontosil seems to be the most promising of the many derivatives of sulfanilamide

The application of sulfanilamide therapy as reported in the literature is unbelievably varied. No doubt in the final analysis, such ardent widespread usage of the drug will be unwarranted

The frequency of toxic reactions and dangerous drug idiosyncrasies in sulfanilamide therapy demands the close observation of the patient both clinically and by laboratory procedures

The 4 cases presented of otitic hemolytic streptococcal meningitis speak for themselves as to the advisability for adequate, timely surgery and for the administration of sulfanilamide. The one fatality in this group (Case 3) unquestionably had his life prolonged even though not saved by therapy. The response in Case 2 appeared almost perfect

We have every reason to believe that the 2 cases of serous meningitis reported here (Cases 5 and 6) judging from the severity of infection perhaps would not have recovered had it not been for sulfanilamide

Case 7 seems particularly interesting because of its severity and the etiological organism found on repeated spinal fluid cultures

CONCLUSION

After reviewing the recent literature concerning otitic meningitis, particularly the type due to the streptococcus, and the chemotherapeutic drug sulfanilamide we presented 7 cases of otitic meningitis treated during the past year with mastoid surgery as indicated and sulfanilamide. Though the outcome of these cases was not perfectly satisfactory, we

are happy to report such an unbelievable improvement in our end results

LARYNGEAL TUBERCULOSIS SURGICAL TREATMENT INCLUDING COLLAPSE THERAPY

FLETCHER D WOODWARD M D FACS University Virginia

THE indications for surgical treatment of laryngeal tuberculosis have undergone many changes since the comparatively recent and marked advancement of thoracic surgery as applied to pulmonary tuberculosis, and accumulated experience in regard to the treatment of the larynx itself has led to a better understanding of objectives and technique

This study was undertaken with a view to illustrate these facts by comparing a group of 136 patients treated during the 5 year period 1923 to 1928, with a group of 152 patients treated during the 5 year period, 1933 to 1938. Both groups¹ had local surgical treatment, chiefly galvanocauterization, but the first group had practically no collapse therapy, artificial pneumothorax alone being employed in 4.4 per cent, whereas the second group had many forms of collapse therapy applied to 49.3 per cent.

It is now a generally accepted fact that etiologically the larynx becomes involved secondarily to pulmonary tuberculosis with a positive sputum, and that to obtain a negative sputum as quickly as possible is one of the main objectives in treating pulmonary tuberculosis. To this end, collapse therapy has been an important factor in improving prognosis.

Diagnosis and pathology have been well studied and presented in many excellent papers so will not be discussed. The incidence of the complication varies widely depending upon what stage of the disease has been studied. In our group of 288 patients with

laryngeal tuberculosis out of 2,119 patients admitted to the sanatorium, 12.8 per cent had this complication on admission.

It is of interest historically to recall the statement of Sir Morrell Mackenzie in 1880 "The prognosis of laryngeal tuberculosis is always extremely unfavorable and it is not certain that any cases ever recover." There was very little change in this view until Dr George B Wood, of Philadelphia, introduced treatment into this country nearly 30 years ago with the galvanocautery, and his statement, "It is undoubtedly the method par excellence for the treatment of laryngeal tuberculosis, and its use brings to the surgeon that peculiar sense of elation which he feels when, through his interference, suffering and death have been averted," marked a distinct step forward. The widespread use of the cautery, education of the public, building of sanatoria and many other measures have contributed toward an improvement of prognosis in this condition, and now with a clearer understanding of local procedures and the development of collapse therapy we are able to offer a better prognosis in this complication than ever before. In our second group of cases, improvement was obtained in over 50 per cent of the patients and I feel that in the very near future, with the added help of bronchoscopy in the treatment of pulmonary tuberculosis, a much higher percentage of improvement will be obtained. Dworetzky says "The incidence of laryngeal tuberculosis is much diminished, from 25.6 per cent to 14.6 per cent in all cases of pulmonary tuberculosis because of collapse therapy, but it is still 80 per cent in hematogenous or primary tuberculosis."

Table I illustrates the results obtained in these 2 groups. The results show a gain of only 13.2 per cent in those obtaining a negative sputum and a gain of only 8.5 per cent in improvement at discharge, as a result of the

From the Department of Otolaryngology, University of Virginia Hospital.

Presented before the Clinical Congress of the American College of Surgeons, New York, October 17-21, 1938.

¹These patients were all under the care of Dr Frank Stafford at the Blue Ridge Sanatorium & Virginia State Tuberculosis Sanatorium. The laryngeal procedures were all carried out by Dr Habstead S. Hedges and the writer and the thoracic surgery by Dr E. C. Drash of the University of Virginia Hospital. The writer is indebted to them for their collaboration in the preparation of this paper.

Fig 1 A diagrammatic sketch of the larynx before operation, showing the fixation of both arytenoids in the midline by a healed tuberculous cicatrix

Fig 2 A diagrammatic sketch of the larynx after operation, showing the increased airway and movable arytenoids, though some distortion is present

addition of collapse therapy These figures seem somewhat lower than expected because many advanced cases were treated in the second group which were not treated in the first group All who have observed the results of collapse therapy are convinced as to its great value

Table II illustrates the types of collapse therapy employed in the treatment of these 2 groups, and is self-explanatory At present the trend seems to be away from operation on the phrenic nerve and toward pneumothorax, with and without pneumonolysis when indicated, and thoracoplasty

Outside of cauterization, no other surgical procedures were necessary except 3 tracheot-

omies, 1 plastic operation for stenosis, and a number of bronchoscopies

There has fortunately been a tremendous change in our ideas of medical treatment The literature enumerates a great many drugs and other curative procedures, which have all had their advocates in the past, while now, other than anesthetic sprays for the relief of pain, the use of chaulmoogra oil as advocated by Lukens, and a few palliative remedies, no other form of medical treatment is used Voice rest remains as one of the greatest aids in obtaining healing and should still be prescribed in all cases

The surgical treatment has likewise undergone great change In the past such pro-

TABLE I—COMPARATIVE ANALYSIS OF 288 PATIENTS TREATED FOR LARYNGEAL TUBERCULOSIS AT BLUE RIDGE SANATORIUM

	Gr up I 1913-1918	Group II 1919-1928
Total number of patients	1090	1133
Laryngeal tuberculosis number	136	152
Laryngeal tuberculosis per cent	12.5	13.4
Sputum positive on admission—per cent	65.6	60.1
Sputum positive on discharge—per cent	63.2	50.2
Cauterization of larynx—number	19	29
Cauterization of larynx—per cent	14.0*	19.0†
Collapse therapy number	6	75
Collapse therapy per cent	4.4	49.3
Improved on discharge per cent	44.1	52.6‡

An additional 10.5 per cent improved with artificial pneumothorax only.

*Results show a gain of 13.2 per cent in those obtaining a negative sputum on discharge.

†11.0 per cent improved when all types of collapse therapy were used.

‡There was a gain of 8.5 per cent in improvement at discharge as the result of the addition of collapse therapy.

cedures as thyrotomy, curettage of ulcers, and even laryngectomy were advised in acute and active cases. None of these would find a sponsor today.

SURGICAL PROCEDURES

Among the surgical procedures used today, we find the following:

1. Galvanocauterization is the most valuable. The indications and technique have been well described by George B. Wood and Joseph B. Greene in various publications, and I need only add that when properly used the results are most gratifying both to the patient and to the surgeon. However, one must remember that too deep and extensive cauterization about the cords and arytenoids may produce stenosis either through inflammatory swelling or by subsequent cicatrization. The results of cauterization in suitable cases by following the sedimentation rate have been well shown by Greene.

2. The local removal by direct laryngoscopy of tuberculous tumors may be necessary at times and differs in no way from other surgical procedures done by direct laryngoscopy except that light cauterization of the base of the tumor seems wise, in order to prevent a local spread of the disease through the traumatized tissue and lymphatics. Radiation therapy by the roentgen ray should be helpful in some cases of this nature.

TABLE II—COLLAPSE THERAPY

	Gr up I Number	Gr up II Number
Pneumothorax		
Without pneumonolysis	6	35
With pneumonolysis	0	14
Phrenics		
Temporary	0	13
Permanent	0	9
Thoracoplasties		
Partial	0	1
Complete	0	1
Totals	6	12

3. Biopsy will be necessary in some instances in which there is a question of syphilis or carcinoma. Cases of this nature have been reported by Gabriel Tuckar and others. And the writer recalls a case of advanced pulmonary tuberculosis in which biopsy showed a tuberculous ulceration and carcinoma in the same section. This patient likewise had a strongly positive Wassermann, but syphilis was apparently not involved in the laryngeal lesion. A carefully done biopsy should not be contraindicated, but light cauterization of the base would again seem to be advisable.

4. Incision and drainage of abscesses either within the larynx or subcutaneously from chondritis of the laryngeal cartilage should be carried out when necessary in the same manner as abscesses from other causes are handled.

5. The removal of the epiglottis has been done many times when disease was far advanced and painful and has given satisfactory results either by punch forceps with cauterization of the base or by snare and the coagulating current.

6. A block of the internal branch of the superior laryngeal nerve has been repeatedly done for the relief of pain, but since the use of the cautery and collapse therapy we have not found it to be necessary in a single case reported in this series. An occasional temporary block will at times be advisable, but one should never advise resection of the nerve itself.

7. Tracheotomy will be necessary for laryngeal dyspnea in rare instances but never with the idea of putting a larynx at rest in order to promote healing, for neither objective would be obtained. The indications for tracheotomy are still those of laryngeal ob-

struction, and in tuberculosis, we find that ulceration and edema, caused either by disease or too extensive cauterization, will necessitate tracheotomy in acute cases, and for tuberculomas, cicatrization, and paralysis of both cords in chronic cases.

The technique of the operation is the same as for any tracheotomy, except that a two stage operation is preferable. As always, a tracheotomy should be anticipated and done as an elective procedure in an orderly manner under aseptic technique. It has been our custom to dissect carefully down to the trachea and expose it completely at the site for the introduction of the tube, then pack the wound open with gauze and partially close the skin. From 3 to 5 days later, the wound is re-opened, the gauze removed, and the tracheal tube inserted without difficulty. By following this procedure, the tissues are protected by granulations, and we are much less likely to get a secondary infection about the wound and skin. This method has been employed in 3 cases of laryngeal tuberculosis and in many other cases of lung suppuration without ever having an infected wound. Meyerson reported 9 tracheotomies, among which the indications were tuberculoma, necrosis of the thyroid cartilage, ulcer and infiltration of the glottis, fixation of both vocal cords by paralysis, fixation of both cords by scar tissue, and fixation by ulceration and infiltration.

8 Cicatricial stenosis of the larynx can be caused by healing of tuberculous ulcers in the interarytenoid space and surrounding region; too active cauterization in this region may also tend to a similar condition. This unfortunate condition is seen at times with an arrested pulmonary infection and often condemns the patient to a life with a tracheal tube, unless some form of plastic operation can be done in order to restore the airway. Since most of the tuberculous ulcerations are seen in this locality, it is not surprising that this problem is met at times.

In the consideration of this problem, one must be sure that the stenosis is due to cicatrization and fixation of the arytenoids and not due to paralysis of the vocal cords. In either event, a tracheotomy should be done, and if we have an arrested pulmonary lesion,

a plastic repair after the method of Schmiegelow can be done, or, in the latter condition, we may gain an adequate airway after the method of Looper by the interposition of the end of the hyoid bone between the edges of the divided thyroid cartilage.

When there is scar in the posterior commissure and fixation of both arytenoids in the mid line, dilatation under direct laryngoscopy is not advisable because of the repeated trauma in a healed tuberculous lesion; but both airway and voice can be restored by thyrotomy, the careful removal of scar tissue by cup forceps, and the introduction of a rubber tube after the method advocated by Schmiegelow.

This procedure has been done repeatedly with uniformly good results for laryngeal stenosis from other causes, but because of the nature of this lesion, it has not been advocated. However, we carried it out on 1 patient with good results, and if we have an arrested pulmonary lesion and a healed cicatrix in the posterior commissure with fixation of both arytenoids in the mid line, I see no reason why it should not be applied to all similar cases.

This operation is readily carried out under local and light basal avertin anesthesia; the tube is well tolerated, and since the ends of the fixation silver wire are buried under the skin, there is very little pain. However, a feeding tube will be necessary for a few days in order to maintain sufficient nutrition, and the tracheotomy tube should be left in for several weeks until we are sure that an adequate airway has been obtained.

9. Bronchoscopy is rapidly being recognized as a valuable adjunct in the treatment of pulmonary tuberculosis, especially when there is involvement of the bronchi and trachea, also for diagnosis in questionable cases, and to furnish valuable information to the thoracic surgeon.

Kernan has reported many cases in which bronchoscopy was useful in treatment and, in summing up, says, "We have the treatment of ulcers by coagulation, silver nitrate, and the quartz rod, of strictures by stretching with copper ionization; of tubercular tumors by removal with forceps or coagulation, of ob-

struction, either by a mass of mucus or a mass of cheesy material in cavities or by a mass of cheesy material in ruptured glands, by aspiration, of secondary abscess or of bronchiectasis beyond structures by aspiration."

Bronchoscopy, by its value in treating pulmonary tuberculosis indirectly, may help the laryngeal lesion, and, I believe, it will occupy an increasingly important place, as time goes on, in the general treatment of tuberculosis. An interesting paper on the pathogenesis of tuberculous tracheobronchitis was presented by Bugher, Littig, and Culp

10 Collapse therapy in some manner was carried out in approximately 50 per cent of all patients during the past 5 years. Out of a total of 1,139 admissions to the sanatorium, 568 had collapse therapy, against 48 out of 1,090 patients admitted during the 5 year period 1923 to 1928. Of course pneumothorax without pneumonolysis represents the greatest number, 331 patients having this form of collapse. With pneumonolysis the number was 82, phrenics temporary were 84, phrenics permanent, 51, thoracoplastics partial, 15, and thoracoplastics complete, 5.

Because of the many facts enumerated, we have felt that it was time to review the question of laryngeal tuberculosis and to evaluate the various surgical procedures used today in treatment, giving the results obtained in a

closely controlled group of patients along with the conclusions we have reached by experience, and to point the way for future guidance, for although we may feel some degree of pride in reporting over 50 per cent improvement, as compared to Dr Mackenzie's gloomy statement of nearly 60 years ago we must remember that there is still a long way to go before we may allow ourselves more than a small degree of pride.

A STUDY OF MEDICAL AND SURGICAL AIDS TO HEARING

JAMES A. BABBITT, M.D., F.A.C.S., Philadelphia, Pennsylvania

MUCH in the general field of otolaryngology has reached a certain stage in finality. The management of acute and chronic sinusitis, allergy, focal control in the Waldeyer ring, peroral endoscopy, mastoid surgery, and plastic reconstruction, would seem to have been largely accomplished; and the student, zealous for pioneer work, simply delves farther back in the embryological field or forges a little ahead with greater care and precision in already well beaten paths.

In the department of otology, however, after rather conclusive investigations in petrositis, otitic meningitis, and labyrinthine vertigo, there has occurred almost a renaissance in the medical and surgical attention to progressive deafness, a transition from the ineffective routine tubal politzerization to a combined biochemical, mechanical, and surgical attack upon this great problem. This strikes a responsive note in a large group of people, who venture the thought, "Am I growing deaf, and what am I going to do about it?"

The purpose of this paper is to group, analyze, and discuss informatively the whole problem of deafness, including its recent rather dramatic surgical episodes. Mechanical appliances, so adequately investigated by Fowler, Newhart, and the Council on Physical Therapy of the American Medical Association, need be discussed only in reference to the patient's psychological attitude. These fundamental topics are suggested for consideration (1) medical management in deafness, (2) readjustment in upper respiratory tract from physiological and focal standpoints, (3) deafness and chronic otological infection, and (4) otosclerosis and fistulization surgery.

MEDICAL MANAGEMENT OF DEAFNESS

It is the intention to discuss deafness upon a broad basis, accepting research conclusions on acoustics, the mechanical variations in

bone conduction, histological changes in the organ of Corti, etc., without sharing in the intricate research which has formed them. Deafness for the purposes of this heading refers chiefly to the popular form of progressive deafness, of the so called dry or catarrhal type, more often combining conductive and perceptive elements. One is accustomed, somewhat inaccurately, to associate conductive disturbance with the middle ear, which includes the eustachian tube, tympanic cavity, and mastoid area, and also to associate perceptive loss with the cochlea and its neural connections with the brain centers. Emerson, however, in 1924 left a lasting impression of his conception of the interrelation of these elements, in a paper under the caption, "Is Chronic Progressive Deafness a Rhinologic or Otologic Factor?"

The examination of a patient with a view to medical readjustment should be more painstaking and with a far broader scope than an ordinary routine, upper respiratory review. Accurate tests for degree and type of deafness should be carefully recorded, and the last word on familial information and the patient's environment obtained.

This basic study must include various factors in nerve damage, as suggested by Hughson, acute infections with neural influence, drug poisoning, congenital influence, nutritional, vitamin and dietary imbalance, occupational hazards, endocrinopathies, hypothyroidism and dyspituitarism, and central nervous system lesions, producing cochlear degeneration by cutting off blood supply rather than affecting the auditory nerve, which is not supposedly susceptible to the *Spirocheta pallida*. Dean and his associates have published a convincing thesis upon allergic diseases of the ear with its special relation to labyrinthine disorder.

Preliminary work in deafness prevention has been done by a group of investigators, notably Covell in San Francisco, Dorothy Wolfe in St. Louis, Taylor in Jacksonville,

and Mosher in Boston, with their masterly demonstration of the prenatal influence of drugs on the neuro-otological perceptive apparatus. *This fits in with the preventive and eugenic programs of child hygiene.*

The psychological factor in deafness is of great medical importance. In a recent communication from Friesner, quoted by permission, occurs the following:

"If one reasons about hearing, one rapidly comes to the conclusion that hearing is an extremely complex mechanism. It is a process that is part physical, part psychical, and curiously enough is influenced by factors both physical and psychic that have no direct relationship to hearing, depend not only upon the reception of nerve stimuli aroused by vibrations in the end organ, but also upon the facile interpretation of these stimuli. Any factor that upsets the mental or physical well being of a patient with a hearing defect disturbs hearing even though the ear mechanism is unaffected and remains as before. The psychic element in deafness is a tremendously important one. Unhappiness for a day may seriously disturb the hearing and yet on the following day the hearing may have returned to normal obviously this cannot be accounted for by any change in the peripheral organ. Deafened patients who hear with a smile do much better than others with similar hearing defects who constantly grieve."

The nutritional index in deafened patients has claimed increased attention in recent years. Added stimulus has come from the impressive contributions upon vitamin and nutritional deficiencies so carefully presented by Selfridge in California. It will be seen what careful physiological and biochemical study of each patient must be made, including careful laboratory analysis of vitamin deficiency from A to G, phosphorus, cholesterol, and serum proteid estimation, x-ray studies of the long bones, and basal metabolism with routine blood and urine analysis.

It is but fair also to refer to the patient work of Jarvis and other nutritional groups in studying the ordinary dietary unbalance. A recent communication from him states:

A continued study of the body process of cell oxidation has revealed that when a block in cell oxidation is present clinical conditions appear in epiblastic tissues of which the ear is one. Applying the theory of a block in cell oxidation I find that children brought in by mothers with the statement "my child is asking over and the school teacher tells me he does not hear well at school, are easily

straightened out. They are asked to exchange wheat foods which are difficult to oxidize for rye bread and corn meal foods. They are asked to exchange white sugar for a monosaccharide represented by honey. They are asked to exchange milk, as a beverage for grape juice and water, equal parts."

Cod liver oil containing organic iodine and arsenic, two good oxidizing minerals, is advised.

Crowe, with a certain dread finality, considers high tone deafness present in the fourth decade of each individual's life, and that it progresses regularly through each succeeding decade. Selfridge, however, believes that optimum nutrition can delay progress of eighth nerve degeneration when recognized early and permanently corrected, and that it is possible after the fifth decade to ameliorate deafness if the tone range from 240 to 4096 double vibrations is not hopelessly damaged. Here the remarkable result of Furstenberg's salt free diet and ammonium chloride administration in Meniere's complex should also be mentioned.

With an enthusiastic assistant, Dr. Silcox, an analysis has been made of the results of routine nutritional and vitamin care in a series of over 100 office patients in whom the effect of vitamin B complex was carefully studied. It seems fair to assume that the changes in audiometric record as reported indicate the effects of the administration of tablets containing vitamin B₈₀ and vitamin G 25 Sherman units, combined with iron and administered 3 times daily over a measured period. There was almost immediate response to the initial administration with sometimes dramatic improvement. However, after varying periods of time, the hearing dropped back in some cases, suggesting that the early administration was in the nature of a neurophysiological stimulus which needed further nutritional support.

READJUSTMENT OF UPPER RESPIRATORY TRACT FROM PHYSIOLOGICAL AND FOCAL STAND-POINT

That known focal infections in the upper respiratory tract, as well as gastro-intestinal, genito-urinary and the general lymphoid distribution, may profoundly affect both per-

ceptive and conductive integrity in the acoustic tract is indisputable. In the upper respiratory tract this concerns sinuses, teeth, the entire Waldeyer tract, pyriform fossæ, and the middle and external ear.

Ever since the expressed views of Logan Turner, Leland, Emerson, and others, confusion of opinion has persisted as to the exact contribution of lymphoid pathology to progressive deafness. The explanation of frequent disappointment in the relief of routine tonsillectomy and adenoidectomy rests in the compensatory hypertrophy of this pharyngeal tissue, poorly covered and easily re-infected from postnasal secretions sweeping down over them in acute or chronic sinus infection. Good tonsil surgery will include the removal of not only these masses but also of the small masses of lymphoid tissue at the base of the tonsillar fossa. A small triangular punch is recommended for this purpose. It is surprising how inconsequential the evidence of "punch" appears on the pharyngeal wall 48 hours afterward, and how little additional discomfort is given the patient. If these compensatory masses need only slight attention, a light coagulation diathermy while producing temporary discomfort will soon remove the trouble.

Schenck has presented a careful paper on chronic infections in the pharynx with demonstration of pathological slides in cases of articular pains, choreiform manifestations, cervical adenopathy, myalgia and nephrosis, which certainly suggest toxemic relation to our progressive deafness.

In addition to the relief of focal toxemia, there would seem to be an important field in the study of physiological readjustment in this tract. For example, the closely approximated septum and middle turbinate in the presence of marked septal deviation, in its disturbance of respiratory aeration and drainage, its possible influence in the distortion of tissue arrangement around the eustachian tube mouth, hyperplasia of turbinate structures covering sinus areas on the concave side of the nasal septum, vasomotor imbalance in the upper nasal chambers, secondary influence of hypertrophy and fibrosis upon the mucous membranes of the sinus cavities, pharyngeal wall, and even eustachian tube, are all matters

of as much physiological importance as the developmental abnormalities attendant upon the high-arched palate of the mouth breather.

The tradition has grown to condemn tonsil and pharyngeal lymphoid tissue removal, as well as sinus and septal surgery in advancing deafness, with the same finality as the useless routine of tubal politizerization. The same obsession against the readjustment of the nasal septum before 16 or 17 years of age disregarded the serious consequences of nasal block in early childhood.

DEAFNESS AND OTOLOGICAL INFECTION

There are many variations under the title of otological infection which deeply concerns the function of hearing. An insidious type of infection is the almost quiescent chronicity, with intermittent drainage, in a middle ear filled with sclerotic tissue. Perhaps among the most important are sequelæ of faulty mastoid and middle ear surgery when adequate technique would have conserved hearing. Mosher, Friesner, Page, Boies, Smith, and others have rendered invaluable service in their teaching of complete surgery. This otological housecleaning in chronic infection deserves just this emphasis for both its reparative and preventive function.

Mastoid procedures by the external postauricular route have been related adequately elsewhere. Chronic middle ear suspicion in suitable cases invites the endaural approach. Preliminary steps include the careful cleansing with iodine and alcohol of the canal approach. Evidences of atresia, small, deep exostoses, eczematous crusts and granulomas must be cared for first, and, as these are chronic cases, there is no need for premature haste. Measures of option are then the complete or total ossiculectomy, some form of modified attic drainage in which free drainage from the antrum down through the posterior half of the tympanic area is secured, and the Tobey procedure of combining ossiculectomy and lateral mastoid drainage.

Lessons from the fistulization technique and from Smith's recent modification of mastoid procedure, suggest the combination of attic and antral drainage with removal of the incus or the head of the malleus in cases in which

resistant attic infection complicates that of the middle ear. This procedure, preferably by the endaural route, opens the mastoid antrum at a point two thirds of the way down from the spine of Henle to the posterior margin of the tympanic ring. The antrum and diseased adjacent mastoid cells are carefully cleared away, the external semicircular canal and then the incus are exposed and may be removed. The conventional radical mastoidectomy does lower hearing, does not overcome all subsequent drainage, and because of granulation tissue and fibrosis, or actual labyrinthine damage imperils the function of the internal ear. The procedure described should preserve the hearing by protecting the normal aditus, producing a flexible ossicular chain and maintaining a normal posterior tympanic wall.

The character of the tympanic perforations, central lateral wall, and attic must influence to a large extent the choice of procedure. The central tends toward self limitation, the lateral wall especially in the neighborhood of the eustachian tube, permits constant re-infection and the attic perforation, either anterior or posterior contributes toward the walling off of cholesteatomatous material, which in the attic antral area produces a tumor like pressure often with grave osseous wall disturbance. Single and multiple perforations invite ingenuity in the obtaining of coalescent and adequate drainage.

OTO-SCLEROSIS AND FISTULIZATION SURGERY

This combined heading heralds the most remarkable surgery of the ear today. Far developed by Holmgren in Sweden and Sourdis in France, the recent demonstrations of the new Lempert approach and technique have brought the problem close to able surgeons in America. The purpose of this paper is to crystallize basic facts relative to a successful fistulization. The important question at issue is the permanent maintenance of mobility in the labyrinthine fluid, in other words the prevention of the closure of the fistula by osteogenetic change.

Historically, according to Holmgren fistulization dates from 1876, when Kessel removed the stapes in order to replace the footplate

with a movable scar membrane. Passow experienced the same results in 1897 by trephining the promontory. A group of famous otologists, including Politzer, Moure, Siebenmann, Botey and Denker, were found to be in opposition to the stapes extraction.

Barany in 1910 opened a fistula in the posterior vertical canal. In 1913 Jenks opened the horizontal semicircular canal twice, covering one with a Thiersch and another with a metal flap, but returning deafness discouraged him. Holmgren began using magnifying glasses in 1920, making a fistula in the promontory, but this, too, closed. In 1922 he had better success with a macro-perosteal flap from the ampulla. At the time of his report in 1937, he had done about 34 human cases in 15 years, and of late was using gold leaf prosthesis covered with fat. Upon the principle of decompression of the labyrinth, he made fistulas to horizontal and posterior semicircular canals and sometimes even to the anterior vertical. Immediately following operation, some vertigo appeared which disappeared within a month. Tinnitus disappeared during the operation, but in failure of maintenance of hearing turned its own return with that of healing in the general operative field.

Sourdille, in 1937, presented his new fistulization technique for the surgical treatment of otosclerosis. In his discussion he first mentions 2 other schools of surgical attention: (1) the Wittmaack-Heynatz-Rollin method designed to combat the perilymphatic venous stasis, he suggests calling it the 'elevation of the supra tympani dura mater', (2) the Alonso Chiarino method of removing one parathyroid or suppressing its function by ligation of its principal vessels.

The operation of Sourdis was originally in 3 stages and by postauricular incision. The first 2 stages were devoted to mastoid excision, exposure of the external semicircular canal and preparation of a reconstructed tympanic system. His operation termed "tympano-labyrinthopexy" consisted in joining the covering membranes of the labyrinthine fistula with the superior border of the tympanic membrane whose excursions have been increased by the removal of the

malleus head The incus is preserved in its place, and, according to Holmgren, acts as a mobile prop and permits displacement of the whole system Sourdille's operation, according to his report, has been performed on 109 patients, with 10 times or more previous hearing distance in 40 per cent, 5 to 10 times previous hearing distance in 14 per cent, mediocre results of 2 to 5 times previous hearing distance in 20 per cent and no fatalities—in other words, 54 per cent of definite improvement

Lempert of New York has developed the one stage procedure via the endaural approach, and in July, 1938, reported operations on 23 patients, 4 of whom had a bad background Nineteen showed good practical improvement, but the canal remained open in 22 of the 23 cases Since this report, he has added 36 fistulization operations, making a total of 59 In all but 9 of these cases the fistulas have remained open In a recent visit to New York to observe his technique, we personally reviewed 20 of these cases Of these 20 operated-upon patients, after a varying period of from 3 weeks to 9 months, all had well healed flaps and 19 of the 20 a good fistula reaction The one weak test followed an otitis media complication Of course these were favorable cases, selected for our review All the patients appeared optimistic and some showed the exhilaration euphoria to which ear patients are prone At the time of our review there was insufficient time to test the improvement of each patient with the audiometer, but there were unquestionably results sufficiently favorable, to be a source of great stimulation for future work

An estimated analysis of endaural fistulization in this country, by other operators than Lempert, gives a total of 30 cases, 8 of which thus far give promise of favorable results, 6 apparently had labyrinthine complications, and the remainder showed doubtful gain over the pre-operative status, but there were no fatalities

While somewhat difficult to place chronologically, mention must be made of a patient reported in 1935 by J S Fraser of Edinburgh, upon whom he had done a radical mastoid and fistulization 17 years previously The bony

cap of the lateral canal was removed and a graft applied with a favorable hearing result and a positive fistula test after 17 years

These results have been presented to indicate that from a surgical standpoint this operation reasonably points to success While somewhat tedious, two facts are definite, as stated by Canfield in his discussion at the American Otological Society's meeting, first, that the fistula increases the air-borne sound, and second, that human beings do not incur undue surgical risk and are only moderately inconvenienced by the operation

The operation presents to an observer about 5 important steps one, the exposure through a mastoidectomy of the horizontal semicircular canal, two, the skeletonizing of the anterior and posterior epitympanic areas for liberating the tympanic sulcus, three, the isolation and removal of the malleus head, four, the careful burring into the semicircular canal, a saucer or trough-like excavation, to relieve the endosteal retention without injuring the membranous canal, and five, the application of a careful flap, constructed from fibrous scar tissue, mucoperiosteum, tympanomeatal or Shrapnell's membrane, to close the fistula adequately The cases selected should be definitely otosclerotic cases or combined progressive deafness closely simulating them, without mastoid or posttympanic infection

Otosclerosis, according to Cahill, clinically presents an ankylosis of the stapes, progressive deafness usually bilateral, and a severe tinnitus, yet with normal drum membranes and patent eustachian tubes. It must satisfy the Bezold triad of lengthened bone conduction, a negative Rinne test, and elevation of the lower tone limits, and there should probably accompany it the paracusis of Willis, meaning the ability to hear conversation better in the presence of a noise, and the pinkish tinge over the promontory representing the active, underlying osteoporosis Its etiology is variously assigned to familial transmission, toxemia, infection, adolescence, or the pregnancy complex

It is appropriate to present the endaural work of Hughson in closure of the round window for the aid of hearing in progressive deafness His work has always been so careful

and scientific that it deserves most thoughtful consideration. In his opinion, "the demonstrated extent of nerve involvement and its probable cause are alone the standards where by operability can be determined. Routine loudness balances, repeated bone conduction audiograms with appropriate masking, supplemented by fatigue tests, give accurate information as to the amount of the organ of Corti and nerve remaining." When this has been established, he feels that fixation of the round window by graft increases the intensity of tone stimulus. He has presented the results of 25 operations for blocking the round window niche with a tissue graft. No further impairment occurred in any and a maximum of 20 per cent improvement was obtained in 1 patient, with an average increase of 10 decibels in all critical frequencies. This improvement occurs later than in the fistulization procedure. Wishart, in his admirable discussion, has commended Dr. Hughson's painstaking and accurate work but questions the ultimate fate and value of the graft.

In conclusion we have tried to give parallel incidents in the nutritional, the upper respiratory, elimination of infection, fistulization, and round window graft aids to hearing. There is apparently not too wide a difference in the measured results of each though there is a wide variance in the dramatic finesse involved. It may be that composite decision will prefer ultimately to accept the value of the greatly improved mechanical devices and educate the sensitive deaf to accept a hearing apparatus as they would a toupee or false teeth. Nevertheless it is hoped that this discussion will increase in the surgeon's faith in vitamin and nutritional possibilities, hope for the slowly demonstrated improvement in upper respiratory correction and charity toward the pitfalls and by-passes of labyrinthine fistulization.

THE PHYLOGENETIC DEVELOPMENT OF THE EAR

J M ROBB, M D, F A C S, F R C S E, and HAYDEN PALMER, D M D, Detroit, Michigan

KNOWLEDGE of the phylogeny of the human ear involves a study of the organs of hearing of nearly related contemporary species as well as of species as remote in relationship as their occurrence in time

The fact that in many insects there are highly specialized organs for the production of sounds indicates that insects possess also the function of hearing. The sound-producing organs of grasshoppers and crickets probably produced the first not merely accidental and functionless sound in the history of life. It serves principally to bring the sexes together. The sound is produced by the friction of a file on the under side of the left forewing over a ridge on the upper side of the right

Auditory organs in their simplest form consist of fine rods suspended between two points of the integument and connected with nerve fibers. This morphological unit may or may not be associated with a tympanum. The peg-like rod, with nerve attached, is known as the scolopophore. The wall of the scolopophore is composed at either end of 7 ribs, each of which is divided in the central portion, making 14 ribs. The entire scolopophore is bathed in fluid and is free to vibrate.

In other species, more elaborate organs are developed. In grasshoppers, highly specialized ears are situated, one on each side of the first abdominal segment. The tympanum is conspicuous as a thinned portion of the body wall. Closely applied to the inner surface of each tympanum is a ganglion known as Muller's organ. Intimately associated with Muller's organ are two horny processes (bone conduction) and a pear-shaped vesicle. Near the margin of the tympanum there is a spiracle, or the Eustachian analogue, which admits air to a space inside the tympanum, or the tympanic chamber. As the nerve endings in Muller's organ are attached to the tym-

panum, it is classed as a chordontal organ of the integumental type. The other type of chordontal organ ends free in the body cavity.

In the long-horned grasshoppers, known as locusts or katydids, and in the crickets there is a pair of tympana near the proximal end of the tibia of each foreleg. Some forms present an external canal. Within the legs bearing these tympana there are chordontal organs. There is also a trachea in each leg of a locust. The tracheas in the forelegs are remarkable for their great size and for the division into two branches. These two branches reunite beyond the end of the chordontal organs.

There are really 3 distinct types of chordontal organs, or cochleæ, in each foreleg of the locust. In the supratympanal form there is a ganglion composed of nerve endings which are scolopophores of the integumental type. Immediately below this is the intermediate organ in which the scolopophores are of the subintegumental type. Third, there is Siebold's organ, or crista acoustica, on the outer surface of the large trachea. This consists of a series of scolopophores which diminish in length toward the distal end of the organ. It forms a ridge on the trachea, therefore the name, "crista acoustica."

The hearing mechanism of the mosquito is connected with the antennæ. At the bottom of the antennæ is an enlargement, the scape, in which the muscles lie. Just above the scape is a greater enlargement, the pedicle holding Johnston's organ or the auditory apparatus, which differs in the two sexes, being more highly specialized in the male. Briefly, this organ consists of whorls of scolopophores, with their attached nerves. Experimentally it has been shown that the different whorls, which decrease in length on successive segments, are caused to vibrate by different notes (Mayer, 1874). It was formerly believed that the great specialization of Johnston's organ in male mosquitoes enabled the males to hear the songs of the females. But it has been

THE PHYLOGENETIC DEVELOPMENT OF THE EAR

J M ROBB, M.D., F.A.C.S., F.R.C.S.E., and HAYDEN PALMER, D.M.D., Detroit, Michigan

KNOWLEDGE of the phylogeny of the human ear involves a study of the organs of hearing of nearly related contemporary species as well as of species as remote in relationship as their occurrence in time

The fact that in many insects there are highly specialized organs for the production of sounds indicates that insects possess also the function of hearing. The sound-producing organs of grasshoppers and crickets probably produced the first not merely accidental and functionless sound in the history of life. It serves principally to bring the sexes together. The sound is produced by the friction of a file on the under side of the left forewing over a ridge on the upper side of the right

Auditory organs in their simplest form consist of fine rods suspended between two points of the integument and connected with nerve fibers. This morphological unit may or may not be associated with a tympanum. The peg-like rod, with nerve attached, is known as the scolopophore. The wall of the scolopophore is composed at either end of 7 ribs, each of which is divided in the central portion, making 14 ribs. The entire scolopophore is bathed in fluid and is free to vibrate.

In other species, more elaborate organs are developed. In grasshoppers, highly specialized ears are situated, one on each side of the first abdominal segment. The tympanum is conspicuous as a thinned portion of the body wall. Closely applied to the inner surface of each tympanum is a ganglion known as Muller's organ. Intimately associated with Muller's organ are two horny processes (bone conduction) and a pear-shaped vesicle. Near the margin of the tympanum there is a spiracle, or the Eustachian analogue, which admits air to a space inside the tympanum, or the tympanic chamber. As the nerve endings in Muller's organ are attached to the tym-

panum, it is classed as a chordontal organ of the integumental type. The other type of chordontal organ ends free in the body cavity.

In the long-horned grasshoppers, known as locusts or katyids, and in the crickets there is a pair of tympana near the proximal end of the tibia of each foreleg. Some forms present an external canal. Within the legs bearing these tympana there are chordontal organs. There is also a trachea in each leg of a locust. The tracheas in the forelegs are remarkable for their great size and for the division into two branches. These two branches reunite beyond the end of the chordontal organs.

There are really 3 distinct types of chordontal organs, or cochleæ, in each foreleg of the locust. In the supratympanal form there is a ganglion composed of nerve endings which are scolopophores of the integumental type. Immediately below this is the intermediate organ in which the scolopophores are of the subintegumental type. Third, there is Siebold's organ, or crista acoustica, on the outer surface of the large trachea. This consists of a series of scolopophores which diminish in length toward the distal end of the organ. It forms a ridge on the trachea, therefore the name, "crista acoustica."

The hearing mechanism of the mosquito is connected with the antennae. At the bottom of the antennae is an enlargement, the scape, in which the muscles lie. Just above the scape is a greater enlargement, the pedicel holding Johnston's organ or the auditory apparatus, which differs in the two sexes, being more highly specialized in the male. Briefly, this organ consists of whorls of scolopophores, with their attached nerves. Experimentally it has been shown that the different whorls, which decrease in length on successive segments, are caused to vibrate by different notes (Mayer, 1874). It was formerly believed that the great specialization of Johnston's organ in male mosquitoes enabled the males to hear the songs of the females. But it has been

From the Departments of Ear, Nose, and Throat of Harper and Herman Kiefer Hospitals

Presented before the Clinical Congress of the American College of Surgeons, New York, October 17-21, 1938

found that in some species at least the females seek the males. Rudyard Kipling may not have had this in mind. The fact remains, however, that the distinctive feature is the presence of scolopophores, which is characteristic of the auditory organs of other insects. The grasshopper has its hearing mechanism in the abdomen, the cricket, in the foreleg, the mosquito, in the antennae. Apparently, nature has cared very little where she put this organ so long as it functions.

When and in what form, did this function of hearing first appear? Who was the first listener? If a fish is sensitive to vibrations of similar frequency in the water, is that analogous to hearing vibrations in the air? And, if so, is the sensitiveness of an earthworm to vibrations in the surrounding soil similar—and the earthworm has a head brain—or must we classify it as a different sense? The sense of hearing and the sense of touch are closely allied and it is hard to draw the line between them and to differentiate which shall be called hearing and which not. In certain insects, however, a real sense of hearing exists which is in some way comparable to our own. In fact there is a striking similarity of mechanism manifest in the parallel development of the invertebrate and vertebrate lines.

The earliest ear structures are associated with the static and kinetic labyrinth. The invertebrate crayfish, a glorified worm and descendant of the trilobite, has a statolith, and it most probably appeared upon the scene earlier than the vertebrate lamprey and hagfishes with their utricle and sacculus. The sacculus becomes progressively differentiated into the lagena and eventually into the cochlea. The utricle and semicircular canals show far less change. With the substitution of air for water the invertebrates develop a more delicate mechanism, as demonstrated in the scolopophore. Inasmuch as scolopophores are found in the worm or embryonic stage of some flies it would seem to predicate the presence of hearing elements in very early extinct forms. The premise of this conclusion rests in the fact that the embryo in its development repeats the history of the race and so in this instance it would carry the function of hearing back to an aboriginal wingless stock.

Let us view in retrospect in order to make a reckoning in geological time. For instance consider the Archeozoic or pre Cambrian period, 1,850,000,000 years ago according to Schuchert and Dunbar, when the diggerminal forms were just getting under way, or just a little later, perhaps when the mid Cambrian trilobite was flourishing 6,000,000 years ago. Some forms of these Crustacea have remained unchanged generically over the same span of time and swarm in the oceans today illustrating the principle of balance or stability of type. While fossil forms would indicate that the harlequin fly developed this side of the Carboniferous period, 300,000,000 years ago, still the presence of scolopophores in this fly's larva as might, as mentioned, point to the occurrence of the same in an early form and at an early date. And so it seems reasonable for us in this political time and in the current parlance to choose the initials P E 2 (Paleozoic) and push back the first listener a few odd hundred million years.

The central line of fish evolution destined to give rise to all the higher and modern fish types, is found in the typical cartilaginous skeleton, jaws and four fins of the primordial sharks of Upper Silurian time, 500,000,000 years ago. The question, "Does a fish hear?" would seem to be answered with the presence of a primitive lagena. While both the shark and the carp family have primitive lagenae the shark has microscopically more elements.

In the brains of the animal, from fish to man, the cochlea is associated with a center in the mid brain. The conditioned reflex for hearing in fish was established by H. A. Bull and reported in 1930. And we have the familiar example of driving herring into nets with the beating of pans.

We have the seeming paradox of fish with ear bones or ossicles. The system of bones is analogous to that found in higher vertebrates but it connects with the lungs or air bladder and not with the tympanum. For that reason the ossicular chain is limited to the group of lungfish or to the teleosts with an equivalent of the lung which is the swim bladder. The arrangement for this purpose is especially elaborate in the carp or catfish families. Weber, in 1820, described a series of paired

ossicles which he erroneously called stapes, malleus and incus, which, as shown in the carp, connect a part of the inner ear, the atrium sinus impar with the swim-bladder. It is also of interest that the tubular sinus impar, aside from connecting the ossicles with the lagena, also directly connects the two labyrinths. The entire apparatus would then function as an organ of hearing. Weber's views remained practically uncontested for half a century, but recently much has been written both for and against this theory. The bones are not homologous with those of the ear of higher mammals, however, being processes of the anterior vertebrae. Those of higher mammals develop from the multiple jaw bones, as seen in the crocodile or alligator.

The sharks and the lung fish (*squalus acanthus*) are alike in this respect, there is a small canal extending from the labyrinth to the surface of the skull. However, the shark has no lungs or swim bladder and, therefore, no weberian ossicles. The air bladder or swim bladder is closed as an organ of respiration, although it has taken on collateral functions. It picks up vibrations as through bone conduction, transmitting them to the ossicles. It also acts as a hydrostatic organ of equilibrium by aiding in the decompression of air from the vascular content in coming from the deep. In other words, it serves as the decompressor chamber of the caisson worker. It is said that when some of these fish are brought from a depth in a certain European lake the swim bladder becomes so large the fish cannot navigate. However, after being stuck with a pin, they swim in the shoal water perfectly.

Finally, Moreau has drawn attention to the *Trigla* (red mullet), a fish having an air bladder supplied with muscles which serve to make the air bladder produce a sound. So you see, we finally have the fish in the position where he is talking. What does he say?

Certainly through all phylogenetic progress the cosmic processes cease to run down and begin to build up, abandoning old forms and constructing new ones. In like manner, in the amphibian and reptile, the lower jaw produces the analogue of the ossicles in man. Below mammals, an entirely different type of middle ear anatomy is found. The reptiles

show a complex evolution in which the half dozen or so bones of the lower jaw are lost one by one, the three bones closest to the jaw articulation leave the lower jaw and become associated with the skull. The ear structures which, in reptiles, are outside of the skull, in mammals, become enclosed in it. The lower jaw articulates in the alligator by means of an extra bone (the quadrate) as well as with an articular cartilage. In some forms of reptiles, as for example the Anomodontia, the articular bone articulates not only with the quadrate but also, to a large extent, with the squamosa, the quadrate shrinking in size and developing processes which give to it very much the appearance of either the incus or the malleus of the mammalian ear. As a matter of fact, it fits in with a fair interpretation of the parts of embryology. The stapes is the equivalent of the columella in the reptile; the articulare is represented by the malleus, and the quadrate, by the incus. The skull of the mammal differs from that of the lower vertebrates in that it is a more consolidated whole. The numerous parts from which the mammalian jaw ossifies is reminiscent of the former state.

The sense of hearing in reptiles is apparently not very acute, although tortoises and turtles are frightened by noise and can distinguish sounds. If it were not so, they would have no voice, which is very tiny and piping in most tortoises during the pairing season. In most water tortoises the tympanic membrane is thin and quite exposed. Lastly, in *Chelone*, the tympanic cavity is filled with a plug of the much thickened skin, possibly an adaptation to the water pressure when these creatures dive to considerable depths. In the crocodile, the outer ear lies in a recess and thus carries a flap of skin provided with muscles to close the ear tightly. The tympanic membrane is visible at the bottom of the recess and, shining through it, is part of that cartilage which is homologous with the malleus of the ossicular chain. Diverticula from the middle ear penetrate the bones of the rear of the skull and form pneumatic spaces in these heavier regions of the skull. The ear is likewise peculiar in snakes. There is a long columellar rod with a fibrous or cartilaginous pad at the outer end which plays against the

middle of the shaft of the quadrate, an arrangement, which we must assume, produces a thundering noise in the inner ear, since every motion of the quadrate during the act of swallowing conveys the vibration directly to the fenestra ovalis. The tympanic cavity, eustachian tubes, and tympanum are abolished and no external traces of the ear are visible.

The croaking of male frog like amphibia is almost certainly life's first vocal music. The frogs have simple middle ear expansions containing air and apparently there are no diaphragms from the main cavity.

According to Henry Fairfield Osborn, founder and former president of the American Museum of Natural History, the dinosaur had a mastoid. In the field of paleopathology, the dinosaurs, considered extinct reptiles of the Triassic period, 150,000,000 years ago, showed evidence of *arthritis deformans*. It is a matter of reasonable conjecture that the earliest evidence of inflammatory change in bone or mastoiditis might be found, therefore, in this fauna. Why did the dinosaur have a mastoid? The next appearance of a pneumatized mastoid process is found in the anthropoid apes, a development of about 65,000,000 years. Where was the invisible evolution of the hereditary germ carried those 85,000,000 years? Or should this interval be considered as that of the "Dark Ages" of the mastoid?

The birds resemble the reptiles among other things in having no ear trumpet or pinna. Their sense of hearing is acute but it has been observed that many kinds of birds are indifferent even to loud noises. Attention is most readily given to sounds which stimulate interest in an inborn equipment or an acquired association. The parental danger note stimulates the crouching instinct of the young partridge. The semi-circular canals of the ear show some correlation with the perfection of flight. They are better developed in a swallow than in a swimming bird.

In some forms of the owl, the external canal reaches nearly the whole height of the skull, being directed upward and downward. In *Nyctala* this asymmetry extends to the bones of the skull itself. The large ear is apparently correlated with a keen sense of hearing in some cases but not in all. It has been suggested

that the development of the mastoid may be secondary to the pull of muscular attachments. But, consider the owl, his eyes are practically fixed and to change his line of vision he has to move his head which he accomplishes in an arc of 270 degrees. Should he not have the mastoid?

As a proof, among others, that the whale is the progeny of terrestrial creatures, are occasional traces of external ears. The bones related to the organ of hearing, the tympanics and petrous bones, are very solid and dense in structure. Moreover, they are but loosely attached to surrounding bones and are thus easily and frequently lost. In whalebone whales the external canal is blocked by a large mass of wax several inches in length which would greatly interfere with hearing. It is believed that vibrations in the water reach the ear by sacs, given off by the eustachian tubes or by bone conduction. In the seal the external ear has vanished. In the sea lion, the external ear though small, is persistent. The ossicles differ from those of terrestrial allies in their large size and massive growth. In this they have come to be like those of the whales.

Bats are on the lookout, of course, for the sounds of insects and require an acute ear but the fact that their flight is directed by a "sound beam," the echo of the sound they emit, their hearing must be most acute to use these reverberations at the speed they fly.

It cannot be doubted that the increased complexity of the brain of mammals raised them in the scale as does also the delicately adjusted series of bonelets in the middle ear. In connection with the elaboration of the chain of auditory ossicles, it is very usual for mammals to possess a thin inflated bone, sometimes partly or entirely formed out of the tympanic bone, the tympanic bulla.

The tympanic bulla of dogs is often very much inflated, if flatter, as in bears, it is still large and conspicuous. In the bear like *Canis* a fairly typical arctoid bulla is seen, but, as a group, the bulla flattens off toward the bony meatus in the raccoon, the bulla is much smaller, in the polecat, it is fairly swollen but there is a little flattening toward the meatus. In cats, there is a double cavity

in the bulla almost separated by a septum, in the pig, it is divided by many septa into a cancellous structure.

It is convenient to mention, here, a curious fact that white cats with blue eyes are said to be always deaf. Should the mother produce a litter of kittens and any one of them has a single speck of color on its fur, it invariably possesses the usual faculty of hearing, but, if perfectly white, it is invariably deaf.

All the lemurs of Madagascar differ from the African forms in that the tympanic ring is completely enclosed by the bulla ossea, but without osseous connection with the same.

Valsalva, in the seventeenth century, observed that those animals having no mastoid cells have large tympanic cavities or bullas. Phylogenetically, the mastoid cells are not found in animals below the level of the apes. There is a considerable pneumatization present in the chimpanzee and the gorilla. The chimpanzee has no antrum, while the gibbon and the orang have no mastoid process. In the common rhesus monkey the petrous bone is cancellous with cavities connected by many small openings into the tympanic cavity. The arrangement obviously differs from that of the higher apes and man. Various groups of mammals have diverticula from the middle ear into the petrous, squamous bone, or zygomatic arch. Some of the marsupials have actual continuities from one middle ear to the other by means of cancellous tissue, and apparently the sphenoid can be so traversed.

Finally, and briefly, there are 3 groups with diverticula from the middle ear, namely, (1) certain reptiles and birds in which the diverticula are not surrounded by bone, (2) mammals in which the simple diverticula are surrounded by bone, and (3) the great apes in which there are diverticula in cancellous bone. In the human and gorilla there can be no doubt about the terminology, mastoid cells.

Something of the phylogenetic development of the mastoid process as it immediately applies to man, more particularly in his primitive state, is included here.

The recent discovery, November, 1936, of three remains of Peking man has afforded the opportunity of showing here the rudimentary mastoid process of our most ape-like relative,

who lived 600,000 years ago. The elongated low brain case and large supra-orbital ridges show relationship to the apes. Ability to make fire and to use tools, together with the capacity of the brain case, proves the Peking man to have been a human. The mastoid process, shown in relation to the external osseous canal, appears to be more rudimentary and more like that of the ape than that of any known man. It is shown in comparison with the skull of the Peking man, the chimpanzee, the Neanderthal man, and a North China modern.

Later computations on the age of the Neanderthal skull places it at about 200,000 years. It is apparently better developed than the Mongoloid or Peking man of 650,000 years. *Pithecanthropus* is probably about the same period as the Peking man, or perhaps a little older, but the lower temporal regions are missing. Sir Arthur Keith's projection of this area looks just about like the skull of the Peking man.

In skulls of the modern type, a pyramid-shaped process of bone, the mastoid process, descends immediately behind the ear. To this process certain muscles of the neck, concerned in moving the head, are attached. It is only slightly developed at birth, attaining its full size when the individual has reached adult life. In the gorilla, a mastoid process is present, but, instead of growing downward to form a pyramidal process, it expands into a flange-like plate, forming part of the bony occipital platform on which the muscles of the neck are implanted. The pit or fossa from which the digastric muscle arises is thus left exposed on the anthropoid skull below the mastoid process. In skulls of the modern type, the pyramidal process covers and hides the digastric fossa. In the Neanderthal skulls, the mastoid process does not assume a distinct pyramidal form. In its shape and relations, it is intermediate to the form seen in young anthropoids and to that in men of the modern type. It will thus be seen that in the mastoid region even the Neanderthal skulls show a series of characters which may justly be regarded as simian in nature and origin.

The function of the mastoid portion of the temporal bone has not been clearly determined. The mastoid is not even vestigial as

the vermiform appendix or some other structures, the removal of which has not shortened life or impaired physiological processes. Nature apparently abhors too much cortical bone, preferring a trellis work of cancellous structure paranasal sinuses and, may I add, the cellular structure of the mastoid.

OCULAR MANIFESTATIONS OF ALLERGY

W BYRON BLACK M D F A C S, Kansas City, Missouri

CLOSE observance by practitioners during the early Christian era proved that food for one man was poison for another. In 1796 Edward Jenner vaccinated for smallpox successfully, Magendie produced anaphylaxis by injections of egg white in rabbits, Pasteur used bacterial inoculation, and Flexner's work on anaphylaxis appeared during the latter part of the nineteenth century. A great amount of forward, constructive work has been done by many brilliant men, too numerous to mention. The foreword written by Woods, to *Allergy and Immunity in Ophthalmology*, by Dr Wilmer, gives a beautiful description of the history of allergy.

Following the epoch making discoveries of the phenomena of anaphylaxis, numerous investigations were conducted to determine the relationship of the processes of hypersensitivity to diseases of the eye. These and other experiments have indicated that the tissues of

the eye, like most tissues, take part in the immunological reactions of allergy with the production of antibodies or of cellular reactions not unlike allergic processes elsewhere. They suggested that allergic reactions may be responsible for certain ocular conditions which were attributed formerly to some other cause. Thus, until recently, the only allergic condition which concerned the ophthalmologist was the conjunctivitis accompanying hay fever, since this necessitated differentiation from other types. Recent reports of the possible allergic character of vernal conjunctivitis, and of so called "allergic cataract," as well as the relationship of bacterial allergy to certain inflammatory conditions of the eye have stimulated study of the possible relationship of allergy to these ocular abnormalities.

ETIOLOGY

A disturbance of the endocrine glands has been cited as the cause of every disease of obscure etiology. Spring catarrh is no exception to the rule, and many writers have been

TYPES OF ALLERGIC MANIFESTATIONS OF THE EYE AND ITS ADNEXA

- 1 Allergic conjunctivitis
 - a acute
 - b chronic
- 2 Vernal conjunctivitis
 - a corneal type
 - b lid type
- 3 Cataract
- 4 Sympathetic ophthalmia
- 5 Corneal ulcers
- 6 Focal eye reactions due to bacterial allergy
- 7 Tuberculous infection of the eye
- 8 Lesions of the retina and optic nerve
- 9 Visual allergy
- 10 Ocular headaches due to allergy

ORGANS AND TISSUES INVOLVED IN THE EYE

- 1 Peri-orbital tissues—edema
- 2 Skin of eye-lids and lid margins—urticaria, edema, contact dermatitis
- 3 Conjunctiva—allergic conjunctivitis
- 4 Cornea—allergic keratitis
- 5 Uveal tract—uveitis, cataract
- 6 Retina and choroid—edema with loss of vision
- 7 Optic nerve—edema with loss of vision

struck by the clinical picture of vagotonia presented by their patients—a preponderance of the vagal over the sympathetic element in the vegetative nervous system with lessened suprarenal activity Angelucci (1898) pointed out the frequency of vernal conjunctivitis in persons of a lymphatic type, defining a diathesis characterized by vasomotor lability, tachycardia, lymphoid hyperplasia, and general hypo-adrenalism (Angelucci's syndrome) After him many observers have noted dysfunction of the thyroid, parathyroid, suprarenal, and sexual glands (Lagrange, 1922-35, Santori, 1927, Lemoine, 1929, Lagrange and Delthl, 1932, and others) Vagotonia has been specially stressed by Guerra (1929), Mamoli (1930), Ferrari (1930), and Casini (1932), and it has been associated with infantilism, the status thymolymphaticus, eosinophilia, and a relative lymphocytosis (Rizzo, 1924, Genaro, 1928) It would appear that the evidence is strong that vernal conjunctivitis is frequently, and by no means invariably associated with constitutional disturbances of this type, but it is weak if taken to imply that such a diathesis is itself causative We are on safe ground only if we admit that these factors, about which we know very little, and that

little vaguely and indefinitely, form a suitable soil whereon the disease may readily flourish

The theory that vernal conjunctivitis is a manifestation of an allergy has the most definite evidence to support it, but even that is not conclusive On general pathological lines such an etiology is possible, for the two types of lesions which occur are analogous to other conditions which are almost certainly allergic, the one conforming to the pathology of a phlycten and the other to a cutaneous eczema. The clinical evidence in favor of this hypothesis is considerable, namely, the tendency to attack the young, the seasonal occurrence of the attacks, and the type of secretion with the presence of eosinophils The theory must stand or fall, however, on the evidence of specific hypersensitivity in affected persons, the demonstration of other symptoms characteristic of allergy with a familial tendency, and the response to treatment by exclusion of the allergen or desensitization to it; and while there is a considerable amount of positive evidence available, it cannot be said to warrant universal acceptance

The existence of a specific sensitivity to pollens, animal inhalants, foods, and so on, has been investigated by several workers. Lagrange (1922), Fort (1923), Townsend (1923), Lemoine (1925-29), Weinstein (1931), and others, found that the great majority of patients were pollen-sensitive, others obtained indeterminate results (Teller, 1932), while still others (Guerra Paolo, 1929, Thommen, 1931) failed to confirm them Lehrfeld (1925-32) in a large series of patients found 30 per cent sensitive to various allergens, when given intradermally in large doses, and exhibiting other allergic manifestations He also obtained a recrudescence of the symptoms in the quiet winter period by instilling some of the irritant into the conjunctival sac Its association with hay fever has also been stressed by Townsend (1923), with vasomotor rhinitis by Mamoli (1930), with asthma by Weinstein (1931), and similar evidence has been brought forward by Seefelder (1911), Kruckmann (1930), and others

Acute conjunctivitis The term, allergic conjunctivitis, is employed usually when referring to the acute inflammatory condition of the

conjunctiva which is seen in patients with hay fever. Here, the conjunctival mucous membrane contains cells sensitized to pollen and as a consequence, contact with pollen produces an allergic reaction. This is manifested by a conjunctivitis which may be reproduced easily outside of season by instillation of dry pollen or pollen extract into the eye. The degree of sensitivity and the extent of the contact will determine the severity of symptoms. They may be mild and scarcely noticeable in some patients or be marked and cause considerable discomfort in others.

The most pronounced symptoms of this condition are itching, lacrimation, and some photophobia. These patients frequently report for examination wearing colored glasses. The secretion present is usually watery and thin or possibly slightly mucoid. The latter type is found, as a rule, in the morning on arising and shows a predominance of eosinophils upon examination of the stained smear.

Inspection of the eyes in these patients will reveal definite evidence of conjunctival inflammation, the degree of which depends upon the severity of the reaction. The vessels of the conjunctiva, both around the cornea and beneath both lids, are injected and the mucosa itself looks swollen or edematous either in its entirety or in localized areas. In the severer types, the lower lids may be swollen or puffy, due to the edematous involvement of the loose subcutaneous tissues.

Edematous, loose tissue beneath the lids is often hard to explain to the patients after a negative history of insomnia, excessive dissipation, or kidney disease. It then behooves the ophthalmologist to make a careful check for the offending allergens.

These characteristics may be more marked during hay fever season in all patients. It seems to be the consensus of opinion among allergists, and I have found it true in my practice, that the allergic patient is sensitive to a number of different allergens. Bags beneath the eyes occur more often in adults than in children. In a smaller percentage of patients the eye symptoms will predominate almost to the exclusion of the nasal symptoms which may be very slight or insignificant. This is the type of patient who consults the

ophthalmologist first, because he believes that there is something wrong with his eyes. It is important that the practitioner recognize the possibility that this condition is allergic in character rather than attribute it to bacterial infection or to eye strain.

The differentiation of the type of conjunctivitis seen in hay fever from other forms of acute conjunctivitis is not difficult. The seasonal occurrence, the intense itching and the absence of mucopurulent discharge containing a predominance of neutrophilic leucocytes and bacteria, and the positive skin reaction to pollens, are sufficient to distinguish it from acute catarrhal conjunctivitis or "pink eye" due to infection.

Chronic conjunctivitis. Chronic conjunctivitis of the allergic type, and similar to that seen in patients with acute hay fever is occasionally observed in those hay fever patients in whom the eye symptoms are especially predominant. In these patients the repeated conjunctival irritation results in a low grade inflammatory condition of the lids, which appear thickened and more or less continuously reddened. The acute inflammation subsides usually with the termination of the hay fever season but persists in a mild form throughout the year. The eyelids of these patients show a tendency to stick together on arising, due to the presence of a thickened mucoid discharge. Although the primary factor in these instances is usually a pollen, the possibility of sensitivity to some other inhalant, like dust, feathers ororris root should be kept in mind, especially in those instances in which the eye symptoms are perennial in character. The diagnosis and treatment of this type is similar to the acute form.

Allergic conjunctivitis, of either an acute or chronic type, in some instances may be the result of sensitiveness to agents other than pollen. Examples of such agents are eyelash dyes, tints, cosmetics, and the different chemical solutions, such as butyn, pontocaine, atropine, bichloride, eserine, and pilocarpine. These products produce rather violent reactions in the eyelid and conjunctiva as a result of marked sensitivity. In this instance, the reaction is in reality like a contact dermatitis. Skin reaction by the scratch or intracutaneous

methods is negative, as would be expected. Cosmetics containing heavy metals, perfume, orris root, certain hair dyes, or even silk, may produce a similar reaction in sensitive individuals, although this is likewise uncommon.

Vernal conjunctivitis. There is little or no question among allergists or ophthalmologists as to the allergic character of the conjunctival conditions thus far discussed. Considerable controversy has arisen, however, concerning the possible allergic basis of the condition known as vernal conjunctivitis, also called "spring catarrh" or "vernal catarrh." This condition is a subacute or chronic form of conjunctival inflammation, which begins characteristically with the onset of the warmer months, particularly in the late spring or early summer, and persists usually as long as the warm weather lasts, which accounts for the use of the term "vernal." It is characterized clinically by itching and redness of the eyes, lacrimation, photophobia, and aropy lardaceous type of discharge which causes the eyelids to stick together especially on arising in the morning. Symptoms are usually worse in the late evening and on contact with heat.

Depending upon the location of the lesions upon examination, two distinct types of vernal conjunctivitis have been distinguished. (1) The limbic or corneal type, characterized by the appearance of discrete vesicles occurring at the margin of the cornea. These may become confluent and completely encircle the corneal border, giving it an "icing" or "frosting" appearance. (2) The lid type involves the lids only. Lehrfeld distinguishes three separate varieties: a, simple follicular, b, cobblestone, and c, granuloma. These may be spoken of as separate varieties but some authors think these are just a continuation of the first form. These are all characterized by red eyes, lacrimation, heavy mucoid discharge, itching, and photophobia. Smears prepared from these secretions by Giemsa stain reveal the presence of eosinophiles in large numbers.

The two types, corneal and lid, rarely if ever co-exist in the same patient. The appearance and locations of lesions are different. Itching is less prominent and mucous discharge scantier in the corneal variety. This type usually disappears with the onset of cold

Pollinating Grasses during Vernal Conjunctivitis Season (from May 15 to September 15).

Grass No. III	10 per cent
Combined weeds No. I	70 per cent
Combined weeds No. II	20 per cent

The allergic conjunctivitis which persists may be carried through the winter by vaccines, autogenous and occupational dusts

weather, whereas the lid type usually starts in the early summer months, and ordinarily is due to the early pollinating grasses acting as the offending irritants. A number of these early grasses pollinating from May 15 to July 1, are June grass, orchard grass, Bermuda grass, sweet vernal, and plantain. Carried on from June to August are Johnson grass, timothy grass, and redtop. From August to September there is the continuation of Bermuda, Johnson, June, and plantain. The latter part of September the corneal or limbic type of conjunctivitis may disappear, but there will be a continuation of the lid type by irritations from pollination of short, giant, southern ragweed, truemark elder, burweed, cocklebur, thistle, western water hemp,

lambs quarter, and pigweed Foods, house and occupational dust, and animal emanations, such as horse and dog dander, may act as continuous exciting factors throughout the year

Cataract The possibility that cataracts, especially the type occurring suddenly in young people, may be allergic in origin has been suggested recently The antigenic properties of lens protein have been recognized for many years Various experiments have shown, for example, that beef lens protein is identical in its antigenic properties with the lens protein of other animals, although different from other types of organ proteins

In 1922, Verhoeff and Lemoine suggested that the inflammatory reaction of the eye or endophthalmitis, which occurred in certain patients after cataract extraction or after a second discussion in children, might be the result of an allergic reaction to the lens protein left behind in the chamber They called this type of reaction endophthalmitis phacoanaphylactica and established it as a clinical entity The existence of hypersensitiveness in these patients was indicated by positive skin reactions to lens protein and also by the fact that injection of lens protein extract for purposes of desensitization was followed by rapid subsidence of the inflammatory reaction

These findings have been fully confirmed by other observers, who likewise have shown that certain patients with cataract will give a negative skin reaction to lens protein before operation and a positive reaction afterward, especially if an endophthalmitis develops after operation It is generally agreed, therefore, that the postoperative inflammation following cataract extraction is an allergic phenomenon and that desensitization with lens protein extract is an indicated and valuable procedure in these patients

The relationship of lens protein to the development of cataract, however, is not defined as clearly Attempts have been made to treat cataractous patients with lens protein extract and although either total arrest or definite improvement has been reported in a large percentage of patients, these results have not been confirmed experimentally and are not generally accepted The only suggestive

evidence of a relationship is the report of the successful production of certain lens defects in a strain of guinea pigs, whose heredity had been followed for several generations and in which no lens defects had occurred previously The mechanism by which these defects were produced awaits experimental confirmation

That cataract also may result from an allergic reaction to proteins, other than lens protein, is indicated by the reports of patients in whom the cataract occurred in association with a definite allergic manifestation The cataracts in these patients were always in a association with atopic eczema Positive skin reactions were obtained in nearly all instances These findings have prompted the application of the term, "allergic cataract," or "cataracts associated with allergy," to these cases

In discussing the ocular antaphylaxis Lemoine covered this subject very thoroughly with Verhoeff and McDonald At the present time I am treating 7 patients with bi weekly injections of lens protein¹ sterile solution of 2 per cent from cattle eyes All these patients varying in age from 35 to 72 years, have incipient cataracts They were given a complete physical examination, and after the foci of infection had been eliminated as nearly as possible, special attention was given to the patients' endocrine balance and vitamin intake They were started on a dosage of two tenths of a cubic centimeter with increasing graduate doses to 10 cubic centimeters It is too early, however, to evaluate this problem This work has been done previously by other men claiming various results

Sympathetic ophthalmia The reason for the occurrence of an inflammation of a normal healthy eye in a patient who incurs an injury in the opposite eye has been the subject of considerable controversy Experimental and clinical observations by Elschnig and by Woods have indicated the possibility that this condition likewise may be the result of an allergic reaction, produced by a hypersensitivity to the uveal pigment The latter also has been shown to possess antigenic properties distinct from that of lens protein As evidence of hypersensitiveness Woods reported the occurrence of positive intracutaneous skin

¹Le. protein 111 m. of cts. ed by Sh. D. D. hme. Philadelphia

reactions to uveal pigment in patients with sympathetic ophthalmia, whereas control patients gave negative reactions. He found that negative skin reactions occurred in the acute stages of the disease, just as they did in the tuberculin allergy of acute tuberculosis. On the basis of these findings, Woods used uveal pigment therapeutically in patients with sympathetic ophthalmia and reported favorable effects. These findings, while distinctly suggestive, are not as yet generally accepted.

Corneal ulcers Isolated cases have been reported in recent literature in which an ulcer of the cornea affected an allergic individual as the result of specific hypersensitivity. Lemoine in 1925 reported a series of 6 cases. Parlato reported an ulcer in an individual who had ocular symptoms in association with coryzal symptoms and who was found specifically sensitive to orris root. Allergic therapy including orris root desensitization proved effective. The appearance of such ulcers as the result of specific hypersensitivity is rare and should be suspected only when they occur in a definitely allergic individual. The exciting allergens in Lemoine's cases were both pollens and foods.

Focal eye reactions due to bacterial allergy There is ample clinical evidence to justify the suspicion that certain inflammatory conditions of the eye, notably iritis, are due to an allergy to bacteria present in such foci of infection as the sinuses, teeth, tonsils, gall bladder, etc. That these foci of infection have a definite etiological relationship is rather generally accepted and is proved by the frequency with which their eradication is followed by disappearance of the eye condition, and also by the occasional flare-ups or focal reactions which follow the removal of the infected focus, or the subcutaneous injection of a vaccine prepared from the bacteria cultured from the focus.

Many successful attempts have been made to obtain living organisms from the secondary focus in the eye. It is obvious, therefore, that the ocular inflammation is not produced by the bacteria themselves but is the result of the action of their toxic products.

Tuberculous infections of the eye The relationship of allergy to tuberculous infections of

the eye has been studied extensively. Such infections are always of endogenous origin and occur in previously infected individuals. The exact part played by allergy and immunity in relationship to these ocular infections is controversial.

According to Woods, conclusive evidence indicates that the phlyctenules of phlyctenular keratoconjunctivitis are the result of an allergic reaction of the sensitized surface of the cornea and conjunctiva which may result either from a small early tuberculous focus in the eye or as part of a general hypersensitivity to tuberculin protein from lesions elsewhere in the body. On the other hand, there seems to be no definite evidence to indicate that an allergic factor exists in tuberculous interstitial keratitis or in tuberculosis of the uveal tract.

Lesions of the retina and optic nerve These structures are rarely the seat of primary allergic reactions. They may be involved secondarily as part of a general allergic reaction, as in the case reported by Bedell in which edema of the nerve head and retinal hemorrhages occurred as part of a serum reaction following the administration of tetanus antitoxin. In another case reported by Coca, simple edema of the left macula occurred each summer in an atopic patient who had gastrointestinal allergy and migraine.

Involvement of the retina by edema or of the retinal vessels (spasm) probably accounts for the ocular symptoms accompanying migraine (scotomas, photophobia, etc.). A similar explanation may be given for those isolated instances of diplopia, temporary blindness, or hemianopsia which are the result of allergy to foods like chicken or fish, although the exact mechanism is not known.

Some attempt has been made to attribute certain instances of retrobulbar neuritis to the pressure of the marked edema incident to an allergic reaction in the adjacent ethmoid or sphenoid sinuses. All 6 cases reported by Hansel cleared up with local treatment. These instances are the exception rather than the rule.

Visual allergy to light. This term has been applied to abnormal ocular reactions to ordinary amounts of light. According to Lehrfeld, "It is principally a physical allergy, not in

TABLE I—DIFFERENTIAL DIAGNOSIS

	Seasonal	Secretion	Cytology	Itching	Lacrimation	Photophobia	Nasal secretion
Allergic conjunctivitis— drugs chemicals dust	Any time	Thin watery	Not marked	Not marked	Marked	Yes	No
Allergic conjunctivitis— pollens foods	Summer may persist	Thin watery	Eosinophils	Marked	Marked	Yes	Marked
Vernal conjunctivitis	Spring and early summer	Ropy thick	Eosinophils	Marked	Marked	Yes	Some
Bacterial conjunctivitis	All year	Thick muco- purulent	None	Some	Marked	Yes	No
Trachoma	All year	Thin watery	None	Marked	Marked	Yes	No

any way related to immunological sensitivity but certainly related to urticaria solaris and to urticaria dermatographica. It is not an allergy in the sense that there exist antibodies or reagins which are clinically foreign to the tissue cells."

Lehrfeld points out that tolerance or intolerance and visual allergy to light is intimately associated with the pigment content of the choroid, retina, and iris and that when this is deficient, tolerance to light is also decreased. This can be corrected to a considerable extent by the addition of pigment in the form of tinted lenses. The use of such glasses has been found very valuable for this purpose.

Ocular headaches due to allergy. After a careful correction of the errors of refraction and a search for pathological conditions of the eye, the ophthalmologist is often unable to make a diagnosis of the patient's headaches. It would then be well to take a careful history of the patient with reference to foods, endocrines, vitamins, and so forth. It is well to keep in mind that the eye symptoms may be due to a nasal allergy giving the referred discomfort to the eyes.

DIAGNOSIS

A careful history is of the utmost importance. It gives leads to the offending allergens, which may be preseasonal, seasonal, or perennial. Eye secretion smears should be prepared by means of Giemsa stain. Tests should be made for food, pollen, dust, and so forth, and there should be cut and scratch tests, intracutaneous, passive transfer, mucosal, ophthalmic, and patch tests, and the leucopenic index should be taken. Special attention should be given to endocrine balance and vitamin intake in order to establish

correctly the basal metabolic rate. A questionnaire should be given to the patients to take home and to fill out, and a complete physical examination of each patient should be made.

The diagnosis of vernal conjunctivitis is usually not difficult except in the early stages. The characteristic localization of symptoms to the eyes, the presence of itching, the seasonal occurrence, the typical appearance of the conjunctival mucosa, and the presence of a thick, ropy, eosinophil discharge are diagnostic. In its early states, it may be confused with hay fever or some type of bacterial conjunctivitis. The presence of nasal symptoms, the strict correspondence of the symptoms to the pollinating period of a known plant and the occurrence of definite skin test evidence of pollen sensitivity are sufficient usually to differentiate hay fever of the ocular type from vernal conjunctivitis. Bacterial forms of conjunctivitis are distinguished by the severity of symptoms and the presence of a mucopurulent discharge which contains many neutrophils and bacteria. The only chronic condition of the conjunctiva with which it may be confused occasionally is trachoma. This condition is readily differentiated, however, by the complete absence of itching, the absence of eosinophils in the discharge, which is not of the ropy type, and the lack of a seasonal incidence.

TREATMENT

Symptomatic. Secretion should be removed from the eyes 3 times a day by irrigation with a dropper. The patient is given a 16 ounce bottle of solution containing 1 grain of salicylic acid, 2 grains of zinc sulphate, 1 dram of sodium borate, 1 ounce of aqua camphora and distilled water sufficient to yield 16

ounces Although the hydrogen ion concentration of the eye secretion is always high, this seems to give more relief than straight alkaline solutions Ten minutes after each eye is irrigated, there should be the instillation of 1 drop in each eye of the following solution: 1 grain of suprarenin bitartrate, 1 grain of zinc sulphate, and saturated solution of boric acid sufficient to yield 1 ounce. One per cent holocaine solution may be added to this mixture, if desired to control pain This is followed by an ice pack

This, in my hands, has given a great deal of relief. The patient is also asked to take 1 to 2 capsules a day. Each capsule is composed of one-eighth grain of powdered neo-synephrin, one-eighth grain of sodium phenol barbital, 2 grains of aspirin, and 3 grains of powdered lactated calcium This dosage is for adults and is used in proportion to age for children Glasses with polarized lens and calabar lens seem to give better results for photophobia than ordinary colored lens It must be kept in mind that these are palliative, symptomatic measures and a search should be instituted for all the offending allergens, pollens, foods, and dusts

The allergic method of treatment may include dry therapy, the avoidance of the etiological factors, the eradicating of some therapeutic infection, or the application of a non-specific therapy. Any one, or a combination of these various types of therapy, may be required to obtain results

SUMMARY

From the review of the literature and my personal experience in this field, it seems certain that allergies play a very definite rôle in ophthalmology.

Most cases of vernal catarrh occur in children When the age of puberty is reached symptoms of vernal catarrh usually disappear and it is at this time that we have an entire change in the endocrine system of the child Unfortunately, there is no accurate means of determining the function of most of the glands of internal secretion and knowledge of the normal biochemical disturbances is so limited that in most cases it is impossible to come to a definite conclusion.

It would seem that the endocrine balance, with metabolic and biochemical function disturbances, is closely associated or the underlying cause of the allergic manifestations. Allergic patients improve rapidly when endocrines are given with the desensitization process

CONCLUSIONS

1. Allergy plays an important rôle in ophthalmic entities.

2. Endocrine disturbances are usually present with allergic phenomena.

3. Endocrine therapy helps the allergic patient

4. The factors of endocrine balance, metabolic and biochemical functions, vitamins, and heredity, all play a part in the allergic patient's manifestations

I wish to express my thanks to Drs French K. Hansel, Albert Lemoine and John L. Meyers, for their invaluable assistance in compiling this paper

TABLE I—DIFFERENTIAL DIAGNOSIS

	Seasonal	Secretion	Cytology	Itching	Lacerimation	Photophobia	Nasal secretion
Allergic conjunctivitis— drugs chemicals dust	Any time	Thin watery	Not marked	Not marked	Marked	Yes	No
Allergic conjunctivitis— pollens foods	Summer may persist	Thin watery	Eosinophils	Marked	Marked	Yes	Marked
Vernal conjunctivitis	Spring and early summer	Ropy thick	Eos. ophils	Marked	Marked	Yes	Some
Bacterial conjunctivitis	All year	Thick mucopurulent	None	Some	Marked	Yes	No
Trachoma	All year	Thin watery	None	Marked	Marked	Yes	No

any way related to immunological sensitivity but certainly related to urticaria solaris and to urticaria dermatographica. It is not an allergy in the sense that there exist antibodies or reagins which are clinically foreign to the tissue cells."

Lehrfeld points out that tolerance or intolerance and visual allergy to light is intimately associated with the pigment content of the choroid, retina, and iris and that when this is deficient, tolerance to light is also decreased. This can be corrected to a considerable extent by the addition of pigment in the form of tinted lenses. The use of such glasses has been found very valuable for this purpose.

Ocular headaches due to allergy. After a careful correction of the errors of refraction and a search for pathological conditions of the eye the ophthalmologist is often unable to make a diagnosis of the patient's headaches. It would then be well to take a careful history of the patient with reference to foods, endocrines, vitamins, and so forth. It is well to keep in mind that the eye symptoms may be due to a nasal allergy giving the referred discomfort to the eyes.

DIAGNOSIS

A careful history is of the utmost importance. It gives leads to the offending allergens, which may be prescasonal, seasonal, or perennial. Eye secretion smears should be prepared by means of Giemsa stain. Tests should be made for food, pollen, dust, and so forth, and there should be cut and scratch tests, intracutaneous, passive transfer, mucosal, ophthalmic, and patch tests, and the leucopenic index should be taken. Special attention should be given to endocrine balance and vitamin intake in order to establish

correctly the basal metabolic rate. A questionnaire should be given to the patients to take home and to fill out, and a complete physical examination of each patient should be made.

The diagnosis of vernal conjunctivitis is usually not difficult except in the early stages. The characteristic localization of symptoms to the eyes, the presence of itching, the seasonal occurrence, the typical appearance of the conjunctival mucosa, and the presence of a thick, ropy, eosinophil discharge are diagnostic. In its early states, it may be confused with hay fever or some type of bacterial conjunctivitis. The presence of nasal symptoms, the strict correspondence of the symptoms to the pollinating period of a known plant and the occurrence of definite skin test evidence of pollen sensitivity are sufficient usually to differentiate hay fever of the ocular type from vernal conjunctivitis. Bacterial forms of conjunctivitis are distinguished by the severity of symptoms and the presence of a mucopurulent discharge which contains many neutrophils and bacteria. The only chronic condition of the conjunctiva with which it may be confused occasionally is trachoma. This condition is readily differentiated, however, by the complete absence of itching, the absence of eosinophils in the discharge, which is not of the ropy type, and the lack of a seasonal incidence.

TREATMENT

Symptomatic. Secretion should be removed from the eyes 3 times a day by irrigation with a dropper. The patient is given a 16 ounce bottle of solution containing 1 grain of salicylic acid, 2 grains of zinc sulphate, 1 dram of sodium borate, 1 ounce of aqua camphora and distilled water sufficient to yield 16

present in the lacrimal sac or canal, one should consider the possibility of hypersecretion of the tears as a cause for epiphora before attacking the puncta or canaliculi. This can be demonstrated by the Schirmer blotting paper test, other individuals being used as controls, and if the output of the lacrimal gland is definitely increased, one can treat the gland with x-ray, excise the accessory lobe of the lacrimal gland, section the ductules, or inject the sphenopalatine ganglion.

If stenosis of the lacrimal sac or canal is demonstrated by x-ray, some procedure to restore normal function of the drainage apparatus is indicated. Various techniques to accomplish this end have been devised. Many were discarded and later revived to good effect. In the main the acceptable methods may be listed as (1) The external operation, in which an anastomosis with sutures is made through a skin incision between the lacrimal sac and the nasal mucosa, (2) the internal, whereby an opening into the sac is effected from within the nasal cavity, (3) the combined operation of Toti-Mosher, in which the surgical attack is from both outside and inside; (4) the transplantation operation, whereby the sac is lifted from its bed through an external incision and transplanted through a new bony opening into the nose, and (5) giant probing, in which an opening is forced from the sac to the inferior or middle meatus and a drain is left in place.

External operation The external operation dates from the early part of the eighteenth century when an English surgeon, Woolhouse, reported a technique which was later revived in 1904 by Toti and has since been popularized by Depuy-Dutemps and Bourguet. Chandler, in his comprehensive review of this subject, states that it is the most refined of all operations on the lacrimal sac and ranks first in the statistics on successful results.

It is the procedure with which my associates and I are most familiar, and in our hands it has been successful in 27 consecutive operations. These have been done on 24 patients ranging in age from 6 to 72 years. Six operations followed acute attacks of dacryocystitis at intervals of 1 to 6 months with no untoward reaction. Fistulas, which were present in 3

cases before operation, gave no further trouble afterward. One operation was done on a patient with congenital syphilis who also had a perforation of the septum. One young female patient had an obliteration of the lacrimal fossa following an automobile accident, which destroyed the bridge of her nose and necessitated many plastic operations for its restoration, the result in her case was as perfect as the others. A middle-aged male patient lost his right eye and suffered mutilation of his face following a shot gun accident, and the atrophied tear sac was located in a mass of scar tissue a full centimeter from its natural bed in the lacrimal fossa. Although the sac was reduced to the size of a pea, it was possible by traction sutures to make an anastomosis with the nasal mucous membrane and this also resulted successfully.

In one patient only have we been disturbed by the formation of a scar. This was in one of our early cases, a middle aged female of Grecian lineage, who developed a keloid type of bridle scar, which we later attempted to improve by plastic repair but with which we were never quite satisfied. In checking the final results of our limited series we were greatly surprised to find that this patient's answer was the most enthusiastic of all; she was perfectly satisfied with the physiological and cosmetic result.

Many operators with much more clinical material have found this procedure satisfactory in from 95 to 100 per cent of cases. Inasmuch as this is an operation which the ophthalmologist without special training or apparatus can learn to do satisfactorily from the diagrams and description, the technique will be given in some detail here, and the student is referred further to the excellent article by J. J. Corbett. It was this article which induced us to adopt the procedure which in our hands has been quite satisfactory.

OPERATIVE TECHNIQUE

Anesthesia is obtained by the hypodermic injection, approximately one hour before operation, of morphine one-half grain to one-eighth grain and scopolamine, one one-hundredth to one four-hundredth grain, depending on the age and size of the patient.

THE PRESENT STATUS OF SURGERY OF THE LACRIMAL SAC

RALPH O RYCHENI R, M D, F A C S, Memphis, Tennessee

THE patient with chronic dacryocystitis, presenting clinically an epiphora and regurgitation of mucopurulent secretion into the conjunctival cul de sac, brings to the ophthalmologist a condition which is of decided interest and importance. The constant watering of the eye is most annoying and prevents comfortable and ordinary use of the eye at any time, while the integrity of the eyeball is in constant jeopardy as the smallest abrasion, such as follows a foreign body in the cornea, may result in infection, ulceration, and loss of the eye.

This type of inflammation has resulted in a variety of procedures designed by radical means to eliminate the focus of infection in the tear sac, such as chemical destruction by cauterization, excochleation, Paquelin or galvanic cautery, and finally excision or extirpation. All of these procedures have had ardent advocates and have been successful in eliminating the backwash of purulent material into the conjunctival sac, but they have been notoriously unsuccessful in ridding the patient of his epiphora which is the main symptom for which he seeks relief. Statistics from various competent clinicians demonstrate that epiphora persists in as many as 65 to 70 per cent of patients who have had the tear sacs removed, and that nearly as high a percentage of patients are dissatisfied with the results of operation.

The so called medical treatment of lacrimal stenosis by the passage of probes to the nose through the normal passages of the lacrimal drainage apparatus has in general given only temporary relief. One may be elated at one sitting to find that relatively large probes can be passed through the stenosed areas after which fluids pass easily into the nose, only to find at the next visit of the patient that a subsequent reaction has produced a constrict-

tion that does not permit the passage of even the smallest probe without considerable trauma and bleeding. This in effect influences the formation of false passages, scar tissue proliferation, and increased stenosis with considerable discomfort to the patient and, as a rule, leaves him with no permanent benefit.

These experiences have caused most of us to seek some method of re establishing normal communication between the conjunctival sac and the nose by means of some operative procedure which promises a permanent and successful result. Such a result is one in which epiphora and mucopurulent secretion from the lacrimal sac have been eliminated entirely, and in which the patency of the drainage system can be demonstrated by the passage of fluorescein or some similar colored solution from the surface of the conjunctiva to the meatal area in the nose. It is not enough to force fluid to the nose by means of a syringe, the fluid should travel as do the tears in a natural unaided way. To obtain this end it is essential that the puncta, canaliculi, and internal common punctum be left in a perfectly normal condition, for if the capillary attraction of this portion of the drainage mechanism is disturbed, one is doomed to disappointment in proceeding to operate on the sac itself. There has been heretofore too widespread an attack upon the puncta and canaliculi by means of slitting and excision when the pathology really lay more deeply in the depths of the sac and lacrimal canal.

These mistakes need be made no longer as the use of a radio-opaque medium such as lipiodol, bismuth in albolene, or iodipin, injected into the lacrimal sac will by x ray demonstrate the position of any stenosis in the passageway. The first is an excellent solution but the injection should be made on the x ray table as lipiodol passes through the lacrimal sac rather rapidly. If no stenosis is

Postoperative treatment has rarely been necessary although occasionally some crusts will have to be removed from the nose. In our series of 27 cases we have had but one postoperative hemorrhage which required packing the nose, and the nasal pack in this patient was removed the morning following the operation with no further complication. On only 2 occasions have accessory ethmoid cells been encountered. These were exenterated and the operation was carried out in the usual manner without complication. In no case as yet have we found it necessary to remove the anterior tip of the middle turbinate or operate on a deflected septum, although we recognize that in some patients there will be nasal pathological processes which require preoperative treatment or surgery. In 1 patient, previously operated upon elsewhere by the combined method, it was necessary to remove by cauterization an adhesion between the septum and the middle meatus.

Paul Chandler has recently advocated a modification in this operation by preparing 3 mucous membrane flaps instead of 2. He made an incision in the tear sac in the form of a T, with the horizontal incision about 3 millimeters from the upper border extending from the anterior to the posterior edge of the sac. The vertical cut extended from the center of the horizontal incision down to the base of the sac, and as far into the duct as possible. A similar incision was then made in the nasal mucous membrane exactly opposite the sac. Thus 3 flaps were formed, a posterior, a superior, and an anterior. These he united with small silk sutures, usually 1 posterior, 2 superior, and 1 anterior, resulting in an almost solid tunnel of mucous membrane running from the sac to the nasal cavity, and the top of the sac was held up in its proper position. Twenty-two operations which he performed in this manner were all successful.

Internal operation The first report of an operation by the intranasal route was by Caldwell in 1893. The method has been extensively advocated by West who made a large opening into the duct above the inferior turbinate and then later modified it to uncover the entire lacrimal sac without opening the duct. Various other modifications in the mat-

ter of reflection of mucous membrane flaps have been followed by good reports from Halle, Bookwalter, Daily, and others. This operation can be done with satisfaction but presents considerable technical difficulty if properly done. It falls in the class of operations which demand a high degree of intranasal technical skill, the only excuse for which is that no external incision is made. It is not an operation for an ophthalmologist, and many prominent rhinologists feel that it is not as safe a method as the one previously described. Perforation of the orbital wall with cellulitis of the orbit and loss of visual acuity has been reported.

Combined operation The combined operation comprised the external technique of Toti with some intranasal modifications of Moshé, which included the removal of the anterior tip of the middle turbinate and curettage of the anterior ethmoid cells in all cases. In addition, any deviation of the septum was corrected by preliminary operation.

A bony window was made through the lacrimal fossa, the exposed nasal mucous membrane excised, and a similar area cut from the approximating wall of the lacrimal sac. The anterior edge of the sac was sutured to the cut edge of the periosteum over the nasal bone but there were no sutures connecting the nasal mucous membrane with that of the sac.

Failures were common because of poor approximation of the openings in the sac and nasal mucous membrane, closure of the osteotomy, or plugging of the newly formed opening by granulations. Successful results ranging from 40 to 100 per cent have been reported.

Transplantation The transplantation method was devised by Forsmark who lifted the lower part of the sac from its bed, severed it at the duct, and then drew the end of the sac into the nose through a small opening in the lacrimal bone. This was modified by Speciale-Cirincione who made the bony window through the anterior lacrimal crest, thereby avoiding the ethmoid cells. This has lately been revived by Stokes who shortened the time of the operation by using an electric trephine which drilled a hole through the ascending process of the maxilla. Stokes re-

Block anesthesia with 1 per cent solution of novocain with adrenalin is made over the supra orbital, anterior ethmoidal, and infra orbital areas as well as in the line of incision and deeply in the bed of the sac.

A cotton or gauze plug saturated in 10 per cent solution of cocaine and adrenalin, 1:1000, is inserted in the middle meatus of the nose near the anterior tip of the middle turbinate in order to produce anesthesia and ischemia of the nasal mucous membrane, and is left in place until the nasal mucous membrane is exposed by removal of the lacrimal crest.

Illumination of the field of operation is an important factor and I use an electric head lamp for this purpose, although a concave head mirror with a good source of light is sufficient. Bleeding is controlled by the suction tip, a point which has been a great aid in shortening the time of operation.

The skin incision is that commonly used in most external sac operations, starting about 5 millimeters above the internal palpebral ligament passing down over its bony insertion (about 5 millimeters to the inside of the inner canthus) in a line parallel to the lacrimal crest, and terminating at a point opposite the entrance of the nasolacrimal canal.

The internal palpebral ligament is cut, the superficial fascia, muscle, and deep fascia are divided, and the sac exposed and reflected outward as it is lifted out of its bony groove. The sac may be retained in this position by means of a retractor, while a similar retractor holds the structures on the opposite side of the wound well over toward the median line. The retractors are held by one assistant while the other assistant works in the field with the operator. I have found that the use of the ordinary lacrimal sac retractor will obviate the necessity for one assistant if the retractor prongs are entered more deeply into the wound and allowed to engage the subcutaneous tissue just over the sac wall and just above the periosteum of the anterior lacrimal crest.

The next step is the complete removal of the anterior lacrimal crest by means of a chisel. When the nasal mucous membrane is exposed the bony opening is enlarged with Citelli and Kerrison forceps, making an oval

shaped window with the long axis from 10 to 12 millimeters in the vertical plane while the transverse diameter varies from 8 to 10 millimeters. Lately, Arruga has advocated making the opening with a motor-driven trephine. However, the technical difficulties encountered at times with such an instrument are considerable and I have not been impressed with it in my personal experience.

At this stage a longitudinal incision is made in the wall of the sac. The pus or mucus, if present, is removed, and the inner lining of the sac is swabbed with tincture of iodine. The nasal plug is then removed. A vertical incision is made in the nasal mucous membrane, equal in length and directly opposite the sac incision. Three sutures of No 0000 catgut on small half curved atraumatic needles are passed by means of a small artery forceps through the posterior tip of the nasal mucous membrane.

These 3 sutures are held taut while a cut 2 millimeters long is made at right angles to the upper and to the lower end of the vertical incision. This forms a flap which facilitates approximation to the posterior lip of the sac. The 3 sutures are drawn through the posterior lip of the sac incision by the small artery forceps tied, and cut close. Thus the posterior wall of the new lacrimal drainage canal is formed.

After the same fashion 3 more No 0000 catgut sutures are passed through the anterior lip of the nasal mucous membrane with the same forceps and held taut while the right angle cuts similar to those in the posterior lip are made. These sutures are drawn through the anterior border of the sac and in addition through the periosteum and overlying soft tissues. The sutures are then carefully tied. It is this last little feature of the Dupuy Dutemps technique—the suspension of the anterior wall of the canal from the overlying tissue—which aids in maintaining the patency of the new lacrimal canal. Three silk sutures or a subcuticular suture closes the skin incision. An ordinary eye bandage is applied but there is no intranasal dressing. Sutures are removed on the third day, and the bandage is discontinued thereafter. The patient leaves the hospital on the second day.

THE 1938 CLINICAL CONGRESS

THE AMERICAN COLLEGE OF SURGEONS IN RETROSPECT AND PROSPECT ON ITS TWENTY-FIFTH ANNIVERSARY

FREDERIC A. BESLEY, M.D., F.A.C.S., Waukegan, Illinois

THIS, the twenty-fifth anniversary of the founding of the American College of Surgeons, is a milestone in its progress. Let us review the accomplishments of its first quarter of a century. Have the years of planning and of laboring to uplift the standards of surgery produced results? In what directions has the influence of the College been strongly and courageously wielded? In what other directions could that influence have been more powerful, more beneficial, more significant, had our vision been clearer and our convictions stronger?

This is a time for critical self-analysis by the Fellows of the College. We are starting on a new stretch of our journey. We have an opportunity to re-define our objectives and to re-intensify our efforts in the directions in which we appear to be pursuing the right course. Today is the future of which some of us had a vision 25 years ago. The realities around us now are the fulfillment of those dreams of yesterday. In all respects they do not meet our expectations, but not one of us will question that without the dreams the realities would have been far less satisfying. Therefore, we must focus our eyes today on the next quarter of a century. We must dream and plan anew so that the record of the next 25 years' accomplishment, upon which the new generation of surgeons will look back in the year 1963, shall be equally as inspiring, and equally as substantial and impressive as the one we now review.

We have important advantages today over the dreamers of 1913. These are the results of their great foresight. We are solidly organized for smooth functioning. We have

accumulated experience in co-operative effort which gives us confidence. We have acquired a background, a sense of stability, and a feeling of permanence that equip us for accomplishing much more in the future than we have in the past. We have won in the eyes of the profession and of the public a position of unquestioned leadership in our field. This last achievement compels us, as trusted guardians of the sick and injured, to insist that surgeons be guided by the highest professional and ethical considerations. Upon us devolve responsibilities not for our own fellowship alone, but for all members of the profession. Looking to the future, we see no lessening of responsibilities. Rather, as our ideals and our purposes become more widely understood, we see increasing dependence upon the College, by both the profession and the laity.

Our founder and organizer, Franklin H. Martin, set us an example of courage and of persistence that is a wellspring of inspiration. Consider the obstacles he faced in trying to weld a profession, composed of individualists, into a guild organized to curb unethical practices by individuals, and to encourage a co-operative ideal that would necessarily destroy individualism of the old, self-sufficient type. The College stands as a living monument to his success in overcoming these obstacles. He took the spirit of democracy and the spirit of co-operation as ingredients, and mixed a potion strange to the taste of the average surgeon of his day. Many of them drank reluctantly. But time and circumstances, and his own gifts of diplomacy and persuasiveness, were on the side of Dr. Martin, and those surgeons learned to like the potion as they felt its stimulating effects.

In organizing the College Dr. Martin and his associates followed the principles of demo-

Address of the Retiring President, presented before the Clinical Congress of the American College of Surgeons, New York, October 17-21, 1938.

ported very favorably on a series of 43 cases. Patency of the sac is essential and the constriction must not be present above the point of severance else the result will be a failure. It will be an excellent operation for cases of chronic dacryocystitis in which a mucocele is present, but will not serve when the sac is atrophic, when papillomas are present or when the sac wall is involved.

Giant probing. Under giant probings are grouped all methods by which a probe is forced into the nasal cavity, either through the original duct passageway or through a new opening in the lacrimal bone, following which some metallic stylet is left in place for varying periods of time. Such operations were suggested by Koster, Ziegler, Fowler, Dean, and others. Probably the best procedure along these lines is that reported by Spratt who slit the lower punctum and under gas anesthesia introduced a Callahan tube on an obturator through the lacrimal passage. The obturator was withdrawn leaving the thin silver tube open at each end, the lower end under the inferior turbinate and the upper end flush with the conjunctival cul de sac. This may be left in place for months and extracted when desired by grasping the lower end with a hemostat and withdrawing it by a rotating movement which crushes the thin silver tube and permits painless removal. Success with this instrumentation has been high.

From the statistical reports available on the operations heretofore described it seems certain that some form of dacryorhinostomy should be substituted for the operation of excision or extirpation of the sac in cases of chronic dacryocystitis. This latter operation should be reserved for tumors of the lacrimal sac and to my mind, that condition should be almost the sole reason for its application. In this connection one should be on guard not to mistake for tumor of the sac the hard unyielding mucocele sometimes encountered in stenosis of the duct. In our series of 24 patients, there were 5 who some time during their treatment were suspected by my colleagues and myself of having malignancies of the sac. The instillation of saline into the sac, the application of heat externally and persistent massage over the mucocele finally re-

sulted in the discharge of a viscous, glairy fluid from the sac through the canaliculi on the conjunctival surface.

It may be justifiable to extirpate the sac previous to intra ocular surgery, when one is pressed for time, but one may be lulled into a feeling of false security by doing so. Virulent cultures of pneumococci have been grown from the conjunctival cul de sac for weeks after such an excision, and it is justly questionable whether dacryorhinostomy is not the choice of procedure even in this situation.

SUMMARY

The purpose of this paper has been to review briefly the various methods to bring about a favorable solution of the intractable problem of chronic dacryocystitis. Results will vary with various operators and each will continue to use the method which has done well in his hands. But for those who have not been successful in treating this condition and for those who still do extirpation in preference to some form of dacryorhinostomy, I offer the choice of several techniques any one of which has its good points. For the beginner in this field of surgery, the external operation with sutures, which join the mucous membranes of the sac and the nose, will prove to be quite satisfactory. Once he has mastered this technique he may proceed to modifications, but one hesitates to change the form of surgical procedure which has given uniformly satisfactory results in his hands, hence I believe that most new converts will continue to use it.

rienced, highly trained men have worked diligently to secure first-hand, accurate information of many kinds from many sources. Their findings have influenced the determination of policies by the Board of Regents, and the execution of these policies by the administrative executives. The proficiency of these investigators is increasing. In the future it will doubtless be necessary to increase their number as the scope of the College activities broadens to include new avenues of service. It can be stated with some degree of finality that this branch of the College work will grow and become more vital.

Another activity that has bright prospects for continued growth is the Library and Department of Literary Research. A valuable service, constantly improving, is being rendered. The usefulness of the package library service cannot be overstated. In the future the service of the library will be utilized and appreciated even more. By co-operating in securing additions to its collections, the individual Fellow can help to increase the department's ability to serve the fellowship.

The College has used the congress and conference method extensively for educating the profession and the layman. While this work is not handled in a specific department but is participated in by all departments, it is an established activity that, for our purposes today, needs separate consideration. It is an activity that has reached astonishing proportions. The Clinical Congress of the American College of Surgeons is one of the great educational events of the year on this continent. Few regular occurrences of any nature are accorded more attention by the press. This shows that the College has been able, with the co-operation of the press, to arouse a demand for news of advances in surgery. When to this public educational value is added the instructional value to the surgeon himself, it is safe to prophesy that the annual Clinical Congress will have a brilliant future to correspond with its brilliant past.

The miniature clinical congresses, or Sectional Meetings, the idea of which was conceived 20 years ago, have performed in their lesser spheres the same service as the larger congress and have the same outlook for con-

tinued success. The first was held in Butte, Montana, the beginning of a series of meetings which have introduced the College and its work to the American people in their home communities. In the smaller group more discussion and freer expression are possible, and the scientific sessions and operative clinics held in the smaller cities have been valuable supplements to the Clinical Congresses held in the larger cities. The community health meetings, for obvious reasons, have been particularly well attended in the smaller communities, and have unquestionably stimulated confidence in the doctor. Confidence, so engendered, will help the public to seek medical advice more frequently and follow it more intelligently. The public should not be expected to accept medical practices on faith. There is nothing occult or mysterious about modern medicine, its scientific basis should be made more clear to the layman to help him to distinguish between impostors and competent doctors, and between haphazard and correct procedures.

This introduces the subject of public education which cannot be too strongly emphasized as a field which must be cultivated more systematically by the medical profession. The College has already prepared the ground in a more or less incidental fashion through Clinical Congresses, Sectional Meetings, and the publicity arising naturally as a result of its various activities, especially Hospital Standardization. The community health meetings have provided an excellent impetus. However, more of a direct nature must be done. The practice of medicine has never been so prominent in the day's news as it is now. Back of it is a gradual awareness by the public that great things have been occurring in the field of medical science, an awareness that we ourselves have tried to develop; and people want to know more about the new discoveries, the new theories, and the new procedures. They also want to know why they are not all benefiting from these discoveries as they should.

Capitalizing upon this interest, authors and publishers are turning out books and articles that are being read avidly. And what is in them? Much sensation and distortion of facts, merely to enhance their readability and

cratic rule, distributing the executive power among many individuals through a representative Board of Governors and a Board of Regents who would be free from any direct self interest or monetary gain. Thus they assured adaptability and the constant influx of new ideas. The basic principles involved in the welfare of the patient will not change, but the modes of applying these principles are changing constantly with new conditions.

As an illustration, there has arisen of late the important question of graduate training in general surgery and its allied specialties. The College has always been actively interested in the formal education and early training of the surgeon. But lately surgery has been tremendously complicated theoretically and practically by new discoveries, new methods, and modern developments in technique. To obtain the desirable command of knowledge and the necessary skill for precision and safety, the student of surgery today must add a more supervised training to his clinical preparation. Not enough qualified hospitals however are providing opportunities for him to gain such practice. Therefore, the College is assuming the responsibility, which rightly belongs to it to determine the extent of the need and to encourage hospitals to inaugurate a graduate training program in surgery, or to enlarge and improve the one they may have at present. The Board of Regents of the College, by raising the requirements for admission to fellowship for this and succeeding years' graduates, obligated our organization to aid in providing opportunities for the extended training that these higher standards demand.

The established departmental activities of the College since they were carefully based on pressing needs for reform or for research, have produced actual tangible improvements in surgical and hospital methods and environment. Perhaps we should consider whether any of these departments have accomplished the purposes for which they were founded to such a degree that their task is finished. Must the College ever be seeking new avenues of service, or does the future hold boundless opportunities for some of these established departments?

The Department of Hospital Standardization—one of our strongest divisions of endeavor, the achievements of which are so well known that they need no reiteration before this audience—what will be its future? Hospitals, like the human beings who work in them, betray no signs of reaching a state of perfection, despite our energetic efforts to improve them. This is an admission we must make at the outset. It means that the work of the hospital department of the College will never be finished. Changing times will bring only new problems. The department must co operate with the Committee on Graduate Training by continuing to survey, analyze, and plan for the developing of graduate training opportunities in acceptable hospitals. In assuming this responsibility the department is insuring its own happy destiny by multiplying its opportunities for present and future service to the patient in the hospital.

The Department of Clinical Research has likewise made rapid progress and insured its permanent usefulness by seeking and making the most of opportunities for service. Great educational and practical benefits have resulted from the promotion and surveys of cancer clinics, the registry of bone sarcoma, the collection of records on 5 year cancer cures, the surveys and standardizations of medical departments in industry, and the efforts to improve the management of fractures. The Fellows of the College are essentially practical, realistic clinically minded surgeons and in the future they will be guided more and more by the evaluations of advances made in clinical surgery as presented by the Department of Clinical Research. In the past 4 decades much of the advance in surgical therapy has been in the technique of operating, and it may be predicted that in the future increasing study and research will be devoted to the cause, pathology and progress of those diseases which are now and will later be found to be amenable to surgical treatment. The Department has before it an ever widening horizon of usefulness and influence in contributing to the advance of scientific surgery.

The field representatives of the College deserve special acknowledgment for the surpassing value of their services. These expe-

ments participate. Its program has been actuated by a desire to enable the surgeon to play in this joint effort the important part for which his background and services qualify him so that the effort as a whole may be more effective. All plans of the College for the future are being made in this same co-operative spirit.

As for the science of surgery, the College has an ambitious project which typifies its zeal to spread knowledge. This refers to the Hall of the Art and Science of Surgery. As yet there is no distinct building in which to house it, but a site has been acquired on which to build some day, and we dreamers of 1938 see upon it, not the old structure that now stands there, but a fitting monument to the inspiration and zeal of those who have led in the research work of the College. Nor is the project wholly dependent upon imagination for sustenance. An impressive nucleus for the collection of exhibits already exists. It is well arranged for display and bids fair in the not too distant future to outgrow the accommodations for its exhibition in the Administrative Building. The Hall of the Art and Science of Surgery will some day need a building of its own, and many of us, we hope, will live to see it rise.

Chiefly, it is as a moral rather than a material force that we see the College of the future. Our ambition for it is that the quality in which it shall most excel will be that of worthy leadership. It needs no artful phraseology or extensive logic to point out that there is grave need for medical statesmen in the ranks of organized medicine. Men who have a broad vision, and the diplomatic and judicial qualifications which make for leadership, are required to cope with the difficult problems confronting them, which cannot be regarded with indifference and equanimity. It is the

duty of the American College of Surgeons to discover and to develop leaders who will make the influence of the profession felt in improving the whole environment of human life. A large part of that responsibility is distinctly medical, for a high average of health is essential to progress. We in the medical profession are compelled today, for our own good and for the good of society, to pool our problems with those of other social agencies, to the end that the fundamental factor of adequate medical care be a strong impetus to their constructive efforts. We must maintain a flexible mentality. Good health fosters economic self sufficiency, good citizenship, everything that makes a happy life. Therefore, it is our duty to welcome and not to resent the interest being shown in high places in the conduct of medical affairs, it shows appreciation of the importance of the work we are doing and can do. As an organization of surgeons we have before us a great opportunity to throw our experience and our intimate knowledge of the problems back of any effort to provide better care for the patient, with the insistence that the direction of the effort be placed in the hands of a competent medical personnel.

If we make the most of our present opportunities, we face a busy, eventful, new quarter of a century. That is what we want—is it not?—strenuous working programs ahead to call forth our best efforts, to develop us individually and as a strong fellowship striving to serve our generation. The College was erected on an ideal for service, so far we think we have lived up to that ideal to the best of our collective abilities. The prospect is that we shall continue to go forward by holding to that ideal. Hopefully and optimistically we set forth on our new quarter of a century for “it is better to journey hopefully than to arrive.”

increase their selling power. Some of the current, popularized, medical literature is good and is truly educational, but much of it exaggerates the flaws which we all know exist, while it fails to convey the impression it should of the sound features of modern medical practice. As is always the case in such a situation, the attack is read by 10 persons and only 1 will read the answering defense if the profession is sufficiently aroused to prepare one for publication. The result is that we may expect a weakening of public confidence unless direct measures are taken to interpret the doctor aright. When the profession is misrepresented as being more interested in its economic security than in healing the sick, the remedy is to let people know in a more systematic way than we have heretofore attempted, that we are surgeons first and earners afterward, for this is true of the great majority of members of the profession.

This brings us to a consideration of the unfortunate practice of fee splitting which furnishes the public with one reason for the accusation of commercialism. Fee splitting is diminishing, we believe, but it is still quite prevalent. The College has fought it from the beginning. Candidates must sign a pledge not to indulge in it, hospitals in which it is countenanced are not approved, and other professional groups have likewise acted against it. In some instances the agitation has only degraded an open practice to a surreptitious one, so more stringent measures are needed to abolish it completely. The competent physician should have a high enough estimate of his own worth to convince his patient of the value of his services and should not expect what amounts to commission on a sale deducted from the surgical fee. Such a practice endangers the patient because it fosters bargaining, and the only way in which it can be completely eradicated is to educate the public to its evils. The Board of Regents of the College have done much to decrease the practice of fee splitting. It is their clear and pressing duty to eliminate it altogether.

The doctor is handicapped because he can not advertise his honesty, his philanthropy, or his spirit of service the way a man who operates a business can, and so the critics are

unanswered when they point to a practice such as fee splitting, which is really indulged in by only a small minority. Consequently, the medical profession has to use extraordinary measures to regulate the unethical minority, in order that aspersions may not be cast through them upon the entire membership. Through its own organizations such as the American College of Surgeons it has provided for self policing, as well as for the developing of programs for broader and constantly improving service to the patient. To acquaint the public with the work the College is doing is to enlighten it concerning the scientific, humanitarian, and public service attitude that characterizes the typical surgeon who through his fellowship and support decides the scope of its activities.

It is true that the great advance shown by medicine, scientifically speaking has not been quite equalled by medical practice as applied to the needs of all classes of society. This problem, however, is not by any means peculiar to the medical field. It exists in government, in industry, and in education. The progress that has been made in improving the lot of the individual is generally obscured by the far greater progress in theoretical and factual knowledge in almost any field. A parallel can be drawn between this state of affairs and the noticeable lag between almost any man's actions and his professed principles and ideals. We think that the medical profession is trying as hard as any other and perhaps harder than most, to solve the problems arising out of uneven distribution of income which makes its services easily available to a few people, but not obtainable by the great majority in the lower income brackets. It is unquestionably a fact that physicians and surgeons give more service for which they receive no money compensation than any other class of people in modern life, and they give it gladly because of the humanitarian motives that govern them.

The American College of Surgeons has always recognized the advantage of united effort by all groups acting to improve the care of the sick and injured and to promote preventive medicine. This again might be considered a special activity in which all depart

And the truth is the surgical world had great need of such a mandate. May I place before you, very shortly, the proof of this, the setting of that earlier time.

Though the American Medical Association had been founded in 1847 for the betterment of medical education and the control of irregular practice, very little was achieved until in 1904 it appointed a special council for the study of this Medical Education and Hospitals. At that time there were in this Country, 162 medical schools, more than in all the rest of the world put together. And is it any wonder that Henry S. Pritchett, president of the Carnegie Foundation said of these schools, that nearly half were entirely inadequate, and Abraham Flexner declared that our "Medical education includes something of what is best, and all of what is worst, to be found among civilized nations."

And during those years surgery, perhaps, was the greater offender. For brilliant as were many of its exponents, the general standards were low, the prevailing methods slap-dash and ill informed with no general oversight or organization.

Samuel Gross of Philadelphia had published the first complete *System of Surgery* in 1859. Writing in 1876 he declared that "there is not a medical man on this Continent who devotes himself exclusively to the practice of surgery." This was the year, (1876), of the Founding of the American Gynecological Society. It was not until 1880 that the American Surgical Association was formed, and only in 1903 the Society of Clinical Surgery.

As an illuminating corollary we observe that in 1873 there were only 149 hospitals in these United States. In 1934, 61 years later, the number is given as 6,334, with their own hospital association formed in 1899.

This addition of 95 hospitals a year was merely the result of supply and demand, for there developed an enormous increase in the work of general surgery and its specialties, with the rapid creation of sixteen special surgical societies or associations. In all conscience it was rapid—really catching, like the measles. These sixteen societies, however, were separate and distinct, determined in part by the points of the compass, and in part by

the special character of the work. Separate and distinct I say, there was little dealing with one's neighbor, for there was as yet, no common nexus between them. You must forgive these facts and figures for it is only in this way that we gain a true perspective, realize the difficulties that beset us. Assuredly there was a large and disjointed house to be set in order—in Flexner's phrase, "something of what is best,"—and at the beginning of the century abundant need of our college mandate. *Vere scribere est per causas scribere*—to write truthfully is to write in the light of the causes of things. So in 1913, the stage was set.

Two ways were open to us—either to follow tradition and exact a scholastic examination, again an exclusive hierarchy, or on the other hand to create from the beginning a surgical commonwealth, the members to be chosen for their character, actual work, and experience.

I shall always believe that, very fortunately, our young College chose the latter course. For in so doing it drew together the many surgical associations, gave them an axis as it were, and also secured the influence and the weight of the whole profession.

After all, in any arena a "punch" is the thing that counts, and the mandate to impress itself, must have this general strength behind it. Moreover as we all know, an academic distinction may confer no skill in practice, even the author of a surgical text may be, as a surgeon, just a weariness to the flesh.

I make no apology for the early College requirement. Accordingly in the first 2 years we admitted to Fellowship 2,024, established at once a powerful nucleus, to control as it were, our cellular life. Speaking for the College we have had, as yet, no cause to regret it.

Again in my judgment, our College gains no small measure of strength from its democratic form of government. As you know, 50 Governors are elected each year for a triennial term; 17 of these represent the 15 surgical societies, the Army, and the Navy, while 33 are chosen by the Fellows at large. I think you will agree that this makes for a fair, a strong, and cohesive organization.

And now concerning the mandate, how much have we done? What is the accounting of our stewardship?

OUR COLLEGE MANDATE

A Tribute to Allen B. Kanavel

WALTER CHIPMAN, M.D., F.R.C.S. (Ed.), F.A.C.S., Montreal, Canada

ON May 5 our College celebrated its twenty-fifth year its quarter century of service in these two Americas. Very reasonably, I think that we may be proud of the achievement. However, "Wisdom is justified only of her children", or, in other words, this very success carries with it a commensurate increasing responsibility.

While we have already 12,700 of these children, a large fellowship, mere numbers or mere size may be, in and of itself, no special virtue. Quality is the thing that counts, and a set regard for our abiding fitness in this changing world. And it is of this aspect of our college life that I shall speak.

You will remember that our Charter of Incorporation, in somewhat quaint phrase extends 'To All To Whom These Presents Shall Come Greeting'. And to this the 450 Founders annexed our constitution and our by laws bequeathed to us this College mandate. And we Fellows implement this mandate, give our hand upon it (as the name implies,) accept this trust, the privilege, the authority, and the obligation. For as a College we solemnly promise to do what we can for the betterment of surgery: its training and its practice, to improve our hospitals and our medical schools, to make of our College a great clearing house wherein a sound knowledge and a safe technique may be advanced, may be tested, stored, and distributed. It is indeed a reform from within, undertaken to make our surgical world a safer and a better place, the welfare of the patient, the alpha and the omega of it all.

And this is no small domain or no light undertaking. Even in our approved hospitals there are two and one half million operations every year, and how imperative is the need of a wise, a vigilant, and a critical stewardship. I need not say here that good surgery is a diffi-

cult, a responsible, and a painstaking business. To secure this for rich and poor alike is the purpose of this mandate, and it is the sum and substance of our College life.

Our College mandate then, and with a special reference to the life and work of the late Allen B. Kanavel, distinguished Regent.

And first in the name of the College, I extend an added welcome to the Class of '38—the 539 Fellows who have been admitted this evening. Oddly enough, your numbers are approximate to the number of our Founders—the Founders of this College. And our one wish is that you prove yourselves as good as they. This Fellowship confers a twofold blessing: you donate yourselves to our College life stream, a carefully matched transfusion, and in return, to each of you are thrown open the gates of a larger and more useful life.

Thucydides said of the ancient Greeks that they "possessed the power of thinking before they acted, and of acting too," and it is just this power of thinking and of acting that has set its seal upon this later Magna Graecia—our own America.

I can think of no better axiom to govern our College life, the *sine qua non* of any achievement. No one can gainsay that our Founders were men of thought and action. It is sometimes said of Franklin Martin that he dreamed three dreams and lived to make them all come true. And these three were: (a) the publication of the journal, SURGERY, GYNECOLOGY AND OBSTETRICS, in 1905; (b) the creation of the Clinical Congress of Surgeons of North America, in 1910; (c) the founding of the American College of Surgeons, in 1913.

The journal and the congress were the successive steps that led to the foundation of our College. How clearly it now appears to us! Franklin Martin, the great harbinger of our College mandate, now rests from his labors. We owe to him and his a debt we never can repay.

Oration on Surgery presented before the Clinical Congress of the American College of Surgeons, New York, October 17-21.

enced it myself, I also have seen it; and I know

The American Board of Surgery, established nearly 2 years ago, amply corroborates this undertaking. In this way then, we educate and train our future Fellows, and peradventure by so doing we may silence the criticism of, may even satisfy, the dyed-in-the-wool academic mandarin. In any case, we benefit ourselves in this appeasement.

Dr Richard C. Cabot, of Boston, recently observed that the greatest single curse in medicine is the curse of unnecessary operations. Well, the above is the remedy to lift this curse even from the mind of the austere physician, and in raising these standards, we are merely redeeming our promise, fulfilling the terms of our College mandate.

The strength of it all, of course, is derived from the individual fellow, his character, his education, and his work. To the extent of his sixpence, the success or failure of the College, is determined by each and every one of us. And just here how apposite is Carlyle's enunciation that, "what you are, thunders so loud I can't hear what you say."

May I quote to you the following "The failure of any Fellow to conserve the ideals of professional honor, of service to the public, and of self-improvement, will impair more than we realize, the prestige of the College." Thus spoke Allen B. Kanavel in his presidential address here in this city, 7 years ago.

From the beginning, our College has been blessed with outstanding men, men who have guided its policy and given it impetus and inspiration. These have been our "prophets in Israel," and this Chicago surgeon was one of the latest and by no means the least, of these. We do well to learn from such men, to study their lives, their influence, and example.

Born in Kansas in 1874, Allen Buckner Kanavel was graduated from Northwestern University College of Liberal Arts, at the age of 22, and three years later he took there (cum laude), his medical degree. After 6 months of graduate study in Vienna, he returned to Chicago, serving first as an interne at the Cook County Hospital, before becoming associated with the department of surgery at Northwestern University Medical School. Here he was to

spend the working years of his surgical life. Certainly he began at the foot of the ladder, for during the first year he merely supervised the patients' recovery from the anesthetic and was given no opportunity whatever even to observe a surgical operation. However, nothing could dampen his ardor and enthusiasm, and there is a strong satisfaction in recalling, that not so many years later, 19 to be exact, he became professor of surgery and chairman of the department, in this, his old School.

Endowed with skilful hands, he revealed during these first years an enquiring mind and a special aptitude in research.

Very early in his career he became impressed by the haphazard treatment of severe infections of the hand, and so he was led to undertake his famous dissections of the hand and forearm, using the injection of bismuth paste, to determine the relation of the tendon-sheaths, the lymphatic and fascial spaces—the natural channels of invasion. He was engaged on this work for some ten years, and in 1912 he published the monograph, *Infections of the Hand*, now in its seventh edition and a recognized authority throughout the world.

And this was only the beginning. The long list of his contributions to our surgical literature reveals a wide range of investigation and a continued interest in all research. In his practice he was perhaps best described as a specialist in many fields, equally at home in the axilla, head and neck, and the abdomen. His operative work was neat, resolute, and resourceful and Lord Moynihan was led to declare that in any serious operation upon himself, this surgeon was the man to do it. No mean tribute I can assure you! Moreover there were other qualities of the artist in him as expressed not only through his hands, but also by his unusual gift in writing and in speech. He was an admirable teacher, and an outstanding exponent in his chosen profession.

In the midst of this active professional life, Dr Kanavel found time, or made it, for many additional activities. He was one of the five founders of the journal, *SURGERY, GYNECOLOGY AND OBSTETRICS*, and served from its inception to his death on its editorial staff, for the last three years as its editor in chief, he was

We are all familiar I take it, or we should be, with the multiple activities of the College. I shall not enumerate them other than to indicate their wide range of usefulness. I have spoken of our College as a great clearing house, and this truly it has become. For examples, it receives from special committees, annual reports of clinical research of the standardization of hospitals and clinical laboratories, and of all the many problems that confront a surgical training and practice. Here, too, is our own Journal with the *INTERNATIONAL ABSTRACT OF SURGERY*, the *Bulletin* a library of 25,000 volumes with current monographs and periodicals and its Department of Literary Research and, thank you, a "package library" which I am using now. The College has a palatial home, it has held 28 clinical congresses and nearly 200 sectional meetings, it has provided community health programs, round table talks, and a legion of lectures, both popular and scientific.

Why it reads, this curriculum, even as a liberal education. True it has cost the College three and three-quarter millions of dollars. An expensive mandate if you will, but the improvement in our hospitals alone is well worth the money.

This hospital standardization represents the largest work of its kind that has ever been undertaken, the largest, the most far reaching, and beneficent. In a true sense a hospital may be considered the fairest measure of any civilization, for it really shows how we treat the sick and the afflicted, and whether or no we are in any practical way our brother's keeper. This campaign, begun 21 years ago with only 89 hospitals meeting the requirement, now shows 2,621 fully approved. Read Malcolm T. MacEachern's textbook, *Hospital Organization and Management*, published 3 years ago.

From the first this College has been intensely engaged in education—the education of ourselves, the laity, and the profession, it is and always has been a great post graduate school. If any proof were wanting, just read the program of this annual meeting in New York. Everything is here clinical, technical and scientific, and it is no 8 hour day I can assure you. The sorrow is that one cannot be in two places at once, for with this embarrass-

ment of riches, the great difficulty is to choose.

Our College then is a great post graduate school, and in consequence, and for this very reason, it is intimately concerned with all medical education. During these years we have lived in the very midst of an American renaissance, and with truth it may be said that this College has borne a share in the great reform. In this time what a change has been wrought in our medical education! You can not make bricks without the proverbial straw, and now we are indeed proud of our 87 recognized medical schools.

Our chief concern, however, is with the young graduate, the embryo surgeon. How is he to secure the requisite training both in theory and in practice? How is he to spend the years between his graduation and his fellowship? These are the long lean years of his so called "graduate training," the most critical and the most important of the whole surgical business.

Samuel Butler enunciated a great educational truth when he said "don't learn to do but learn in doing." And this mandate so expressed has been for several years of urgent interest to the College. Various committees have been formed and have studied the many aspects of this important question. The junior candidate group was a step in this direction, and as from January 1, 1938, all applicants for Fellowship must have at least 3 years of hospital training and experience. "To learn in doing" under control and supervision and, Fellows of the College, we have promised to find the place.

Progress is a sign of life, we cannot stand still. It seems to me that in this best and natural way we raise the College requirement and make the path straight toward an entrance examination for the Fellowship. Personally I believe in such an examination. Surgery is a science as well as an art, and at some time in his apprenticeship, the candidate is to be examined in the basic sciences—atomy, physiology, and pathology, while later, if you will, he is to present his case reports. The average man is lazy and indifferent—most of us are average—and he needs such an objective such a stimulus, to make him work. I have experi-

enced it myself, I also have seen it; and I know.

The American Board of Surgery, established nearly 2 years ago, amply corroborates this undertaking. In this way then, we educate and train our future Fellows, and peradventure by so doing we may silence the criticism of, may even satisfy, the dyed-in-the-wool academic mandarin. In any case, we benefit ourselves in this appeasement.

Dr Richard C. Cabot, of Boston, recently observed that the greatest single curse in medicine is the curse of unnecessary operations. Well, the above is the remedy to lift this curse even from the mind of the austere physician, and in raising these standards, we are merely redeeming our promise, fulfilling the terms of our College mandate.

The strength of it all, of course, is derived from the individual fellow, his character, his education, and his work. To the extent of his sixpence, the success or failure of the College, is determined by each and every one of us. And just here how apposite is Carlyle's enunciation that, "what you are, thunders so loud I can't hear what you say."

May I quote to you the following. "The failure of any Fellow to conserve the ideals of professional honor, of service to the public, and of self-improvement, will impair more than we realize, the prestige of the College." Thus spoke Allen B. Kanavel in his presidential address here in this city, 7 years ago.

From the beginning, our College has been blessed with outstanding men, men who have guided its policy and given it impetus and inspiration. These have been our "prophets in Israel," and this Chicago surgeon was one of the latest and by no means the least, of these. We do well to learn from such men, to study their lives, their influence, and example.

Born in Kansas in 1874, Allen Buckner Kanavel was graduated from Northwestern University College of Liberal Arts, at the age of 22, and three years later he took there (cum laude), his medical degree. After 6 months of graduate study in Vienna, he returned to Chicago, serving first as an interne at the Cook County Hospital, before becoming associated with the department of surgery at Northwestern University Medical School. Here he was to

spend the working years of his surgical life. Certainly he began at the foot of the ladder, for during the first year he merely supervised the patients' recovery from the anesthetic and was given no opportunity whatever even to observe a surgical operation. However, nothing could dampen his ardor and enthusiasm, and there is a strong satisfaction in recalling, that not so many years later, 19 to be exact, he became professor of surgery and chairman of the department, in this, his old School.

Endowed with skilful hands, he revealed during these first years an enquiring mind and a special aptitude in research.

Very early in his career he became impressed by the haphazard treatment of severe infections of the hand, and so he was led to undertake his famous dissections of the hand and forearm, using the injection of bismuth paste, to determine the relation of the tendon-sheaths, the lymphatic and fascial spaces—the natural channels of invasion. He was engaged on this work for some ten years, and in 1912 he published the monograph, *Infections of the Hand*, now in its seventh edition and a recognized authority throughout the world.

And this was only the beginning. The long list of his contributions to our surgical literature reveals a wide range of investigation and a continued interest in all research. His operative work was neat, resolute, and resourceful and Lord Moynihan was led to declare that in any serious operation upon himself, this surgeon was the man to do it. No mean tribute I can assure you! Moreover there were other qualities of the artist in him as expressed not only through his hands, but also by his unusual gift in writing and in speech. He was an admirable teacher, and an outstanding exponent in his chosen profession.

In the midst of this active professional life, Dr Kanavel found time, or made it, for many additional activities. He was one of the five founders of the journal, *SURGERY, GYNECOLOGY AND OBSTETRICS*, and served from its inception to his death on its editorial staff, for the last three years as its editor in chief, he was

We are all familiar I take it, or we should be, with the multiple activities of the College. I shall not enumerate them other than to indicate their wide range of usefulness. I have spoken of our College as a great clearing house, and this truly it has become. For examples, it receives from special committees, annual reports of clinical research, of the standardization of hospitals and clinical laboratories, and of all the many problems that confront a surgical training and practice. Here, too, is our own Journal with the INTERNATIONAL ABSTRACT OF SURGERY, the *Bulletin*, a library of 25,000 volumes, with current monographs and periodicals and its Department of Literary Research and, thank you, a "package library" which I am using now. The College has a palatial home, it has held 28 clinical congresses and nearly 200 sectional meetings, it has provided community health programs, round table talks, and a legion of lectures, both popular and scientific.

Why it reads, this curriculum, even as a liberal education. True it has cost the College three and three quarter millions of dollars. An expensive mandate if you will, but the improvement in our hospitals alone is well worth the money.

This hospital standardization represents the largest work of its kind that has ever been undertaken, the largest, the most far reaching, and beneficent. In a true sense a hospital may be considered the fairest measure of any civilization for it really shows how we treat the sick and the afflicted, and whether or no we are in any practical way our brother's keeper. This campaign, begun 21 years ago with only 89 hospitals meeting the requirement now shows 2,621 fully approved. Read Malcolm T. MacEachern's textbook, *Hospital Organization and Management*, published 3 years ago.

From the first this College has been intensely engaged in education—the education of ourselves, the laity, and the profession, it is and always has been a great post graduate School. If any proof were wanting, just read the program of this annual meeting in New York. Everything is here clinical, technical and scientific and it is no 8 hour day. I can assure you. The sorrow is that one cannot be in two places at once, for with this embarrass-

ment of riches, the great difficulty is to choose.

Our College then is a great post graduate school, and in consequence, and for this very reason, it is intimately concerned with all medical education. During these years we have lived in the very midst of an American renaissance, and with truth it may be said that this College has borne a share in the great reform. In this time what a change has been wrought in our medical education! You can not make bricks without the proverbial straw, and now we are indeed proud of our 87 recognized medical schools.

Our chief concern, however, is with the young graduate, the embryo surgeon. How is he to secure the requisite training, both in theory and in practice? How is he to spend the years between his graduation and his fellowship? These are the long lean years of his so called "graduate training," the most critical and the most important of the whole surgical business.

Samuel Butler enunciated a great educational truth when he said 'don't learn to do, but learn in doing'. And this mandate so expressed, has been for several years of urgent interest to the College. Various committees have been formed and have studied the many aspects of this important question. The junior candidate group was a step in this direction, and as from January 1, 1938 all applicants for Fellowship must have at least 3 years of hospital training and experience. To learn in doing" under control and supervision, and, Fellows of the College we have promised to find the place.

Progress is a sign of life, we cannot stand still. It seems to me that in this best and natural way we raise the College requirement and make the path straight toward an entrance examination for the Fellowship. Personally I believe in such an examination. Surgery is a science as well as an art, and at some time in his apprenticeship, the candidate is to be examined in the basic sciences—atomy physiology and pathology while later if you will he is to present his case reports. The average man is lazy and indifferent—most of us are average—and he needs such an objective such a stimulus to make him work. I have experi-

COMMENTS ON THE 1938 MEETING

HENRY W. CAVE, M.D., F.A.C.S., New York, New York

THE annual Clinical Congress of the American College of Surgeons is intended, primarily, to be an educational event. Therefore, its success is proportionate to the gains in knowledge and in understanding which those who attend it receive. Of course, it is quite impossible to calculate exactly how much more knowledge the 1938 delegation carried away than they brought with them, but it is entirely possible to judge of the aggregate educational benefits by analyzing the spirit shown at the meetings.

It was stimulating, in the first place, to note the interest in the subject of education for surgery itself, especially graduate education and training. Concern for the preparation of the new generation of surgeons shows appreciation of the increasing complexity of surgical problems. In the second place, it was impressive to see surgeons, who are recognized among the most competent in the profession, eagerly watching other surgeons, perhaps less well known, perform operations and demonstrate procedures. This bears testimony to the fact that the surgeon recognizes that the continual interchange of opinions and experiences is essential to keep him up-to-date and to maintain the required self-confidence for successful surgery. That the Clinical Congress presents a welcome opportunity for such interchange was most apparent, and it seems that every year the surgeon's zeal to learn grows in intensity as more knowledge accumulates.

A change is quite noticeable in the type of knowledge which the surgeon is seeking at the Clinical Congress. In the past he wanted to watch famous surgeons at work or to see unusual and extraordinary operative procedures. Of the 1938 Clinical Congress audiences, however, one surgeon remarked "They seemed to be not so much interested in brilliant, individual results as in a consideration of the commoner problems which confront a surgeon in his daily practice." This means that the mere fact that a problem is common does not imply

Chairman of the Committee on Arrangements

that it is easy to solve, or that, being constantly confronted with it, a surgeon becomes confident that he has learned all there is to be learned. It seems that the opportunities for widening knowledge afforded by this Clinical Congress is steadily increasing its educational value.

Fifty-two hospitals participated in the clinical program, the largest in point of clinics in the history of the Congress. Most of the operative clinics were well attended. A feeling is growing, however, that these have a disadvantage, in that only a few persons standing close to the operating table can see the details of operation. Surgery is becoming less dramatic and more physiological, the dry clinics and demonstrations, together with the scientific sessions and symposia, seem to provide the best media for dissemination of information. Presentation of a subject from all the different points of view, that of the surgeon, perhaps the specialist, the radiologist, the pathologist, the anesthetist, and others, gives opportunity for correlation which is invaluable.

The symposia on cancer, fractures, urological infections, surgical procedures on the handicapped patient, industrial medicine and traumatic surgery, and obstetrics and gynecology demonstrated the progress that has been made in the diagnosis and treatment of these various branches of surgery. The evening meetings, which were addressed by outstanding surgeons, some of whom were foreign guests, were well attended and the subject matters were received enthusiastically. The midday round table conferences were a new feature this year, and were outstandingly successful because of the opportunity they provided for more informal discussion than was possible at the larger meetings.

Wednesday was given over to the Brooklyn Chapter of the American College of Surgeons. In the Brooklyn hospitals a most thorough and complete clinical program was carried out, and the participation of our Brooklyn neighbors added much to the success of the Congress.

treasurer of the Clinical Congress during its seven independent years, and of the College, he was a founder, a governor and a regent, and active member of many committees and finally its president in 1931-32. Through it all, he was always the "man on deck," ready, purposeful, and competent. I can imagine no finer tribute than the one paid to him by his Journal on his sixtieth birthday in commemoration of these services, and of his 35 years of *surgical teaching and practice*.

A full life indeed and full to its tragic end!

All this work of course was the great center of his life but there were nevertheless certain

"margins of leisure" round about it, and these margins only the more clearly revealed the lovable character of the man. He was always a great reader and genuinely attached to books. It is in his library that I best remember him. Again he was fond of games, and of the open and the sky, and especially in his later years Nature in her changing moods, was a great solace to him.

The end came in a motor accident at the age of 64 years. He has passed from the sight of men, but he lives "in minds made better by his presence, and in thoughts that pierce the night like stars."

TWENTY-FIRST ANNUAL HOSPITAL STANDARDIZATION CONFERENCE

MALCOLM T. MacEACHERN, M D, Chicago, Illinois

THE twenty-first annual hospital standardization conference, held in New York City in connection with the Clinical Congress of the American College of Surgeons, was exceptionally well attended, and it was noteworthy for the great amount of instructive and inspirational material which was presented.

Hospital executives showed special interest in the discussions of the College program to increase opportunities for graduate training in surgery and the surgical specialties, and gave assurances of their co-operation. This subject is treated in an article by the chairman of the Committee on Graduate Training for Surgery which appears on another page.

At a joint meeting with the Greater New York Hospital Association 5 of the more important subjects of general interest to hospitals today were discussed: graduate medical education, hospital insurance, standardization of equipment, financial safeguards for endowment funds, and the place of the voluntary hospital in society. In presenting the latter subject, David H. McAlpin Pyle, president of the United Hospital Fund of New York City, said that the element of competition between government and voluntary hospitals should gradually be lessened as it becomes evident that the two types of institutions are really complementary; the one assumes the bulk of the burden for hospitalization of patients of the lowest income class and of those afflicted with illnesses of long duration, and the other serves primarily the needs of those patients who can afford to pay all or something toward the cost of their care. Particularly constructive was his suggestion that the voluntary hospital make available, on a semi-philanthropic basis, the benefits of modern medicine and surgery to the middle classes through both the hospital's in and outpatient departments. This would remedy the fundamental defect in present day hospital service which tends to confine

such benefits to the rich who can pay well for them and the indigent who can pay nothing.

The value of organized voluntary service in hospitals and the co-operation of governmental and voluntary agencies in promoting the welfare and care of the sick is not only desirable but possible under conditions of co-operative leadership in the community. Between them there must be no conflict, is the belief of Dr. S. S. Goldwater, commissioner of hospitals, New York City.

Hospital problems of practically every nature were discussed at the various sessions of the conference, and an entire afternoon was devoted to demonstrations of administrative and technical procedures in local hospitals. At the opening session the progress of hospital standardization was briefly outlined and the customary announcement was made of the list of approved hospitals, based upon the 1938 survey. The list showed a total of 2,664 hospitals fully and provisionally approved. The increase over the 1937 figure of 2,621 hospitals is not large; but more new institutions are included than the difference would indicate, inasmuch as approval was withdrawn from a number of hospitals which had shown laxity in observing certain of the requirements of the Minimum Standard for Hospitals.

Some hospitals were not rated or were reduced in rating because their administrators did not measure up to the requirements of adequate training and experience in hospital administration, some because of evidences of fee splitting, a few because of extension of the privilege of hospital facilities to so called "irregular" practitioners, and others because of incomplete medical records, the use of nurses' aids to perform duties for which they are inadequately trained, and other deficiencies. The announcement redemonstrated the fact that approval is not automatically retained; but continuous effort by the hospital is necessary to remain on the approved list.

Among the distinguished guests from abroad who presented papers at the Congress were William H. Ogilvie, M.D., F.R.C.S., of London, England, who spoke on "Cancer of the Stomach," Professor Hans Finsterer, of Vienna, who read a paper entitled, "Results of Repeated Operations upon the Stomach, Especially Gastrojejunal Ulcers", and Professor Paul Werner, who described the Wertheim operation for cancer of the uterus. Mr. Ogilvie was granted an honorary fellowship.

Motion pictures again proved themselves to be valuable means of instruction. They were presented almost continuously and large audiences were always in attendance.

The link between the surgeon and the hospital, which constitutes his workshop, was again emphasized by the holding of the Hospital Standardization Conference in conjunction with the Clinical Congress. This important branch of the College activities is un-

doubtedly not appreciated sufficiently by the average surgeon, but those who attended the Clinical Congress and noticed the large and enthusiastic audiences at the hospital sessions received an insight into the value of Hospital Standardization.

The relation of the surgical profession to the public through the press has long been considered an important aspect of the Clinical Congress, both from an educational and an interpretive point of view. The local committee on public relations aided the chairman of the committee on public relations of the College in co-operating with the press representatives in the preparation of articles, thus avoiding misinterpretation of scientific facts.

The Committee on Arrangements is most grateful to those who took part in the programs, for their unfailing co-operation, and to those who attended the Congress, for their enthusiastic reception.

TWENTY-FIRST ANNUAL HOSPITAL STANDARDIZATION CONFERENCE

MALCOLM T. MACEachern, M D , Chicago, Illinois

THE twenty-first annual hospital standardization conference, held in New York City in connection with the Clinical Congress of the American College of Surgeons, was exceptionally well attended, and it was noteworthy for the great amount of instructive and inspirational material which was presented

Hospital executives showed special interest in the discussions of the College program to increase opportunities for graduate training in surgery and the surgical specialties, and gave assurances of their co-operation. This subject is treated in an article by the chairman of the Committee on Graduate Training for Surgery which appears on another page

At a joint meeting with the Greater New York Hospital Association 5 of the more important subjects of general interest to hospitals today were discussed. graduate medical education, hospital insurance, standardization of equipment, financial safeguards for endowment funds, and the place of the voluntary hospital in society. In presenting the latter subject, David H. McAlpin Pyle, president of the United Hospital Fund of New York City, said that the element of competition between government and voluntary hospitals should gradually be lessened as it becomes evident that the two types of institutions are really complementary, the one assumes the bulk of the burden for hospitalization of patients of the lowest income class and of those afflicted with illnesses of long duration, and the other serves primarily the needs of those patients who can afford to pay all or something toward the cost of their care. Particularly constructive was his suggestion that the voluntary hospital make available, on a semi-philanthropic basis, the benefits of modern medicine and surgery to the middle classes through both the hospital's in and outpatient departments. This would remedy the fundamental defect in present day hospital service which tends to confine

such benefits to the rich who can pay well for them and the indigent who can pay nothing.

The value of organized voluntary service in hospitals and the co-operation of governmental and voluntary agencies in promoting the welfare and care of the sick is not only desirable but possible under conditions of co-operative leadership in the community. Between them there must be no conflict, is the belief of Dr. S. S. Goldwater, commissioner of hospitals, New York City.

Hospital problems of practically every nature were discussed at the various sessions of the conference, and an entire afternoon was devoted to demonstrations of administrative and technical procedures in local hospitals. At the opening session the progress of hospital standardization was briefly outlined and the customary announcement was made of the list of approved hospitals, based upon the 1938 survey. The list showed a total of 2,664 hospitals fully and provisionally approved. The increase over the 1937 figure of 2,621 hospitals is not large, but more new institutions are included than the difference would indicate, inasmuch as approval was withdrawn from a number of hospitals which had shown laxity in observing certain of the requirements of the Minimum Standard for Hospitals.

Some hospitals were not rated or were reduced in rating because their administrators did not measure up to the requirements of adequate training and experience in hospital administration, some because of evidences of fee splitting, a few because of extension of the privilege of hospital facilities to so called "irregular" practitioners; and others because of incomplete medical records, the use of nurses' aids to perform duties for which they are inadequately trained, and other deficiencies. The announcement redemonstrated the fact that approval is not automatically retained; but continuous effort by the hospital is necessary to remain on the approved list.

The increasing determination to solve the maternal morbidity and mortality problem by constructive measures, which will insure better care, was evidenced in the devotion of an entire session to the discussion of the care of the mother and newborn in a general hospital. This symposium was preceded by the presentation of the minimum requirements of the American College of Surgeons for the obstetrical department in a general hospital.

Another general subject which was emphasized, and an entire session of discussion concentrated upon it, was the training of hospital executives. More and more the necessity is being appreciated of methodic instruction and systematic practical training for persons to whom the management of the hospital is entrusted. Hospital administration is a highly specialized profession. The political appointee who has no firsthand knowledge of hospital problems, cannot possibly direct a hospital in such a way that its maximum potentialities for service may be realized, irrespective of the quality of his general educational and personal status.

Medical records were discussed, as in previous years, in a joint conference with the Association of Record Librarians of North America, as well as in round table conferences. This subject is one which it is necessary to emphasize continuously because complete medical records are not only a means of determining medical progress, but are themselves if properly used, a factor in furthering advances. Unfortunately, all hospitals have not yet recognized the importance of such records. In a few cases correction of this one deficiency would entitle a hospital to a place on the approved list.

In the discussion of the effect of physical conditions in the environment of the patient

as related to his case, and the further influence of these conditions on the personnel concerned special reference was made to the subjects of proper lighting, air conditioning, noise control, color, and other factors which may have a direct or indirect bearing on the progress of disease and convalescence, and on the morale of the hospital personnel.

Of major importance was the discussion of trends in nursing education and nursing service, and the progress which has been made in evaluating criteria basic for good nursing service in the hospital. It is apparent that the art and science of nursing is developing a higher level of standards.

The general tenor of the talks and discussions at the 1938 conference was that hospitals, like most other institutions in this era, must recognize the changing order but must hold fast to the gains which have been made and seek to build upon them. The path of progress for the hospital is clearly marked along certain fundamental lines such as higher qualifications for all types of personnel, more carefully planned organization, greater attention to medical records both in preparation and use, wider coverage of scientific and clinical problems through medical staff conferences, bettering of physical facilities, an increasing sense of obligation in the training of all types of medical and hospital personnel, and a growing spirit of co-operation with all agencies whose efforts are directed toward improving human welfare. All of these considerations are inherent in the principles of Hospital Standardization, which has been the most prominent factor in hospital progress in the United States and Canada for the past 25 years, and which promises the patient constantly improved hospital care as new developments arise and prove their practical value.

GRADUATE TRAINING FOR SURGERY AND THE SURGICAL SPECIALTIES

DALLAS B. PHEMISTER, M D , F A C S , Chicago, Illinois

THE subject of graduate training for general surgery and the surgical specialties was emphasized at the Hospital Standardization Conference and at several of the scientific sessions of the Clinical Congress. The program of the American College of Surgeons is aimed not only toward increasing the opportunities for graduate training, but also toward improving the quality thereof. The subject was presented in considerable detail, and was heartily endorsed by the many speakers who contributed their views. Unquestionably, all agreed that this program is a great potential power toward insuring steadily rising standards of surgery which will benefit the profession, the patient, and the public in general.

In planning a program of such scope and significance, it is to be expected that there will arise some differences of opinion as to the best methods to be employed. It is gratifying that so few criticisms have been forthcoming, and none of these have been of an obstructive nature, but have been the natural result of differences in physical plants, and of differing views as to how the desired ends may be attained, in fact, these criticisms have usually originated from misunderstanding. Through conferences and discussions the College has sought to reconcile the various viewpoints as to details of procedure in order that a program may be developed that is workable and yet flexible enough for adaptation under varying circumstances. Some believe, for instance, that the sort of opportunity for graduate training, which the College considers ideal, cannot be created except in university connected hospitals or very large hospitals with university affiliations. These conditions will gradually be supplied either by plans which are being devised for basic science training in university laboratories, or by co-operation between uni-

versities and hospitals through the exchange of residents so that a wider range of experience may be afforded.

There is no denying that the large city hospital, connected with a university, has an advantage in providing graduate training, since clinical and academic facilities are abundant and highly organized. This is no reason, however, for confining graduate training to such institutions. In the first place, the surveys made by the College prove that they do not provide enough opportunities to fill the existing need for adequately trained surgeons. In the second place, there are some strong arguments in favor of the less centralized, and really more typical smaller institutions as training grounds. In the third place, the communities outside the medical centers are in need of surgeons with good basic science education and some training in the specialties who wish to acquire training in general surgery which can best be gained in the hospital of average size and average equipment.

There is no intention, in striving to improve graduate training, to encourage all medical graduates, who aspire to become surgeons, to seek opportunities in university connected hospitals. Rather there is a pronounced desire to stimulate the medium sized hospital in the medium sized community to devise ways and means of combining its advantages, as a typical field for practical experience, with the facilities for basic scientific study and specialized experience offered by the medical school hospital. Basic science training may be had independent of affiliations with the pre-clinical departments of medical schools. In other words the greatest effect of the whole program can be, if the hospitals and medical schools rise to their opportunity, to decentralize graduate training for surgery, and to make it possible for medical graduates to acquire in the medical center a well rounded, basic science background which they can ap-

SYMPOSIUM ON CANCER

PRIMARY PULMONARY MALIGNANCY

Treatment by Total Pneumonectomy

Analysis of 79 Collected Cases and Presentation of 7 Personal Cases

ALTON OCHSNER, M D , F A C S , and MICHAEL DeBAKEY, M D , New Orleans, Louisiana

UNTIL recently carcinoma of the lung has been considered a relatively infrequent condition. However, recent studies demonstrate that pulmonary malignancy is not only a common occurrence but is one of the most frequent carcinomas of the body. This increase in incidence of bronchogenic malignancy is undoubtedly both apparent and real, as evinced by autopsy series from the German Clinics. Junghanns found an incidence of pulmonary carcinoma of 1.67 per cent of all autopsies performed from 1893 to 1927. The incidence of primary pulmonary carcinoma in all malignancies found at autopsy was 14.27 per cent during the period from 1893 to 1897. Seyfarth found increases in the incidence of pulmonary carcinoma from 5.01 per cent during 1900 to 1906 to 8.75 per cent from 1919 to 1923. During the first half of 1924 there was an incidence of 15.5 per cent. Jaffé, of Chicago, believes that pulmonary carcinoma represents 11.47 per cent of all carcinomas, and that pulmonary carcinoma was second in frequency only to carcinoma of the stomach and of the intestine. Frissel and Knox, in a series of 3,659 autopsies, found 588 cases of carcinoma of which 39 were carcinoma of the lung, thus representing 6.6 per cent of the total carcinomas and 1.06 per cent of the total autopsies. D'Aunoy, Pearson, and Halpert reported that of 6,000 necropsies on persons over 1 year of age, performed in the Charity Hospital in New Orleans, primary carcinoma of the lung occurred in 70, or 1.1 per cent, and was almost as frequent as primary carcinoma of the biliary tract or of the pancreas. In 1,244 autopsies performed at the Touro Infirmary in New Orleans there were 259 cases with carcinoma. Twenty-three of the carcinomas originated in the bronchus. The incidence of bronchial carcinoma in the total autopsies was 1.8 per cent,

whereas that in all carcinomas was 8.8 per cent (36). It is evident, therefore, that the frequency of pulmonary carcinoma is high. The fact that in Jaffé's cases it was second only to carcinoma of the stomach emphasizes the necessity for its clinical consideration.

Although it is controversial whether the increase in pulmonary carcinoma in recent years is apparent or real, the German autopsy statistics would indicate that the increase is actual and not only apparent. There are several explanations for the actual increase in the incidence of pulmonary malignancies, most of which have not been satisfactory. A number of theories have been suggested. Winternitz, Wason, and McNamara, because of the presence of metaplasia in the bronchial mucosa of persons dying from influenza, suggested that this change is a precancerous lesion. The inhalation of irritating gases such as war gas or gas originating from the increased use of motor cars has been proposed as an etiological factor. In our opinion the increase in smoking with the universal custom of inhaling is probably a responsible factor, as the inhaled smoke, constantly repeated over a long period of time, undoubtedly is a source of chronic irritation to the bronchial mucosa. In addition to the actual increase in pulmonary malignancy, there is unquestionably a relative increase in those localities where routine postmortem examinations previously have not been made. This is due probably to the fact that the condition has not been suspected in many cases and adequate diagnostic procedures have not been employed. The recent development of thoracic surgery has stimulated interest in intrathoracic lesions. This, with the development of specialized methods of diagnosis, has facilitated the recognition of pulmonary malignancies.

PATHOLOGY

It is generally agreed that the lining cells of the alveoli rarely, if ever, give rise to malignant neoplastic growths. Consequently all carcinomas of

Presented in the Symposium on Cancer, before the Clinical Congress of the American College of Surgeons, New York, October 17-21, 1938.

ply under competent supervision in the average sized hospital, perhaps even in their home community. Surgeons so trained are more likely than not to remain in such communities, and thus there may result a more decentralization of surgical skill than now exists. The need is acute for more direction in the final stages of a surgeon's training, and for more consideration of just how he is to use his training in the place where he is needed most.

Admittedly, the problems are many. But as one speaker said at the Congress, most of the problems will be removed automatically by the passage of time, since recent graduates in medicine have a much better foundation upon which to build. For a short time, however, some concession must be made to argu-

ments for existing methods, such as training through apprenticeship, when no better system is available and when the senior surgeon is competent and conscientious.

In all fields of life today the trend is toward systematization and organization for efficiency and for progress. Surely in a field in which human life is at stake, methods which are hazardous and unco-ordinated should be unhesitatingly outlawed. The large concepts of safer surgery, better surgery, and increasing conservation of human life demand for their realization that hospitals, medical schools, and the surgical profession unite to further a correlated system of training for surgery which will insure to every community a surgical service of unchallenged quality.

location and the extent of the lesion. Generally, the symptoms are not produced by the neoplasm itself, but are due to secondary changes resulting from its presence. The most constantly encountered symptoms are cough and thoracic discomfort. The latter may vary from a slight consciousness to actual pain within the thorax. In those cases in which ulceration occurs hemoptysis is a prominent manifestation. Whenever occlusion of the bronchus occurs atelectasis, with displacement of the mediastinum toward the affected side, and consequent infection produce marked symptoms. In the peripherally located tumors with extension to the pleura, evidences of pleurisy with effusion may be present. Symptoms which appear late are loss of weight and strength, dyspnea, and osteo-artropathy. Due to the circumferential growth the vascularity of the tumor in its central portion becomes impaired resulting in necrosis and abscess formation. Pulmonary abscess without an antecedent pneumonitis or foreign body aspiration should be considered of malignant origin until proved otherwise. Likewise an unexplained cough and hemoptysis in a patient past 40 years of age should be considered the result of carcinoma until this diagnosis is excluded. The physical findings in pulmonary malignancies are as protean as the symptoms and are dependent upon the location and extent of the lesion and secondary pulmonary changes which may be produced by it.

DIAGNOSIS

The most important factor in the diagnosis of pulmonary carcinoma is the consideration of its possible presence. This lesion invariably should be suspected in every patient 40 years of age or older with unexplained cough, hemoptysis, or thoracic discomfort. While roentgenography, without the use of contrast media, is usually of little or no value in the early diagnosis of non-obstructive bronchial neoplasms, careful stereoroentgenographic studies are necessary in all such lesions. The roentgenographic interpretation of centrally located lesions is generally more difficult because of the confusion with hilar shadows produced by other lesions and normal structures. This is particularly significant because most pulmonary neoplasms occur in the hilar region. In centrally located lesions, after the condition has progressed to such an extent that bronchial obstruction occurs, atelectasis of one or more lobes develops, depending upon the degree of central location. The physical findings and particularly the roentgenographic manifestations of this condition are characteristic, i.e., dullness or shadow

Fig 1 Lining cells of tracheal mucosa of a fetus 12 centimeters long. Beneath the cylindrical cells covering the surface there are several rows of nuclei of "reserve cells." Modified after D'Aunoy, Pearson, and Halpert (13, 26)

and displacement of the mediastinal structures toward the affected side (Fig 6). In peripherally located pulmonary malignancy the roentgenographic diagnosis is dependent upon shadows produced by the infiltrating tumor (Fig 7).

Of greatest importance, as regards accurate diagnosis, is bronchoscopic visualization of the tumor and biopsy obtained by this means. While the microscopic demonstration of malignancy of the bronchus is the ultimate ideal, there may be some difficulty in obtaining a satisfactory specimen. We are in complete accord with Jackson and Holinger that the incidence of correct diagnoses, made by bronchoscopic visualization of the lesion, will probably be higher when made by one experienced in the bronchoscopic diagnosis of these tumors than by routine microscopic examination of biopsy specimens. This in part is due to the recalcitrance of most pathologists to diagnose carcinoma from the examination of a few cells, and it is also due to the fact that the inexperienced bronchoscopist may not obtain representative neoplastic tissue. In every instance, however, an attempt should be made to obtain tissue for microscopic examination, because, as

the lung are bronchiogenic. Carcinomas of the lung have been variously classified according to their morphological appearance. However, the most logical classification to us is that proposed by Béla Halpert. This classification is based upon the development of the cells lining the bronchi and this adequately explains the histological structure of all primary pulmonary carcinomas. Normally, the cells lining the mucous membrane of the bronchial tree represent varying degrees of differentiation and specialization of the original entodermal cells. According to Halpert, 'The epithelial cells covering the mucous membrane of the bronchial tree from stem to the minute branches are entodermal cells with a varying degree of differentiation and specialization. Apparently the undifferentiated entodermal ancestor cell is capable of developing into ciliated cylindrical epithelium, goblet cells, cuboidal cells, arranged into acinar and tubular structures producing a serous or mucous secretion indifferent cells, lining the ducts of these glands and into another kind of cuboidal or low cuboidal cells without cilia which line parts of the terminal bronchioles. In addition to the variety of cells just enumerated there are, beneath the ciliated cylindrical and goblet cells, a varying number of other epithelial cells which like the basal cells in the epidermis, are lined up along the border toward the tunica propria. They are the cells from which the single layer of ciliated cylindrical and goblet cells are replenished. These cells which may be called 'reserve cells' are the parent cells of the ciliated cylindrical, and goblet cells. In addition they naturally also possess the qualities of their ancestor cells in that they may differentiate into any kind of epithelium that an entodermal cell is capable of producing' (Fig 1). According to Halpert, carcinomas of the lung originate from these 'reserve cells' by atypical proliferation.

These malignant growths may, therefore, be classified into 3 types, depending upon the embryological direction of growth: (1) the "reserve cell" carcinoma, (2) cylindrical-cell carcinoma and (3) squamous cell carcinoma. This conception of the embryological development of carcinomas is graphically illustrated by the development of the cells of the bronchial mucosa from a primitive entodermal cell (Fig 2). According to D'Aunoy, Pearson, and Halpert the "reserve cell" carcinomas consist of round, elongated, or polygonal cells growing in solid masses and forming no particular structure. Characteristically they have a palisade arrangement of the peripheral cells (Fig 3). The cylindrical cell carcinomas are

composed of cuboidal or columnar cells forming tubular or acinar structures, or are mounted on delicate connective tissue stalks in a papillary arrangement (Fig 4). The squamous cell carcinomas have a tendency toward keratinization or to pearl formation with central keratinization (Fig 5). A given tumor is as differentiated as its most differentiated part. If one accepts Halpert's classification, it is evident that only the 'reserve cell' carcinoma might be radiosensitive. As these represent, according to D'Aunoy, Pearson, and Halpert, approximately one third of all carcinomas of the lung, it is obvious that relatively few pulmonary neoplasms should on a theoretical basis at least, be radiosensitive. This is corroborated by the poor results obtained from this form of therapy. According to Halpert the gross characteristics of pulmonary carcinoma are in no way dependent upon the microscopic structures, but depend upon rapidity of growth and secondary changes which occur in the tumor such as hemorrhage and necrosis.

As regards the location of primary neoplasia of the lung, the right side is involved slightly more often than the left. In Fischer's series of 3,735 cases of pulmonary carcinoma the right side was involved in 53 per cent and the left in 45 per cent. In 2 per cent the lesions were bilateral. It is of interest that in 46, in which localization was given of the 79 collected cases in which total pneumonectomy was performed for pulmonary neoplasm the right side was involved in 19 or 41.3 per cent, whereas the left was involved in 27 patients or 58.6 per cent. In 784 of Fischer's cases in which the location according to the bronchus was designated the findings were as follows: The right main bronchus was involved in 142, the left main bronchus in 115, the right upper lobe bronchus in 148, the left upper lobe bronchus in 130, the right lower lobe bronchus in 129, the left lower lobe bronchus in 105, and the middle lobe in 15. Most pulmonary neoplasms are centrally located, i.e. of hilar origin. According to Boyd 90 per cent of these neoplasms are in the region of the hilum. In Frissel and Knox's series the incidence of hilar carcinomas was not so high, only 49.7 per cent. Seventeen and eight tenths per cent involved the parenchyma and were of the nodular variety. 6.5 per cent were peripheral, 23.9 per cent were diffuse and 2.1 per cent were bilateral, hilar.

SYMPTOMATOLOGY

There are few or no symptoms in the early course of bronchial carcinoma. The symptoms vary considerably and depend entirely upon the

Fig 4 Cylindrical cell carcinomas are composed of cuboidal or columnar cells forming acinar, tubular, or papillary structures. The parent cells are the "reserve cells" which form haphazard imitations of the normal epithelial cell structure which composes the air passages. Modified after the method of D'Aunoy, Pearson, and Halpert (13, 26)

Fig 5 Squamous cell carcinomas grow in nests of cells in a concentric arrangement forming epithelial pearls with central keratinization. The endodermal cell of the air passages has the quality of producing stratified squamous epithelium. The parent cell of this carcinoma is a "reserve cell" of earlier ancestry than the ordinary. Modified after D'Aunoy, Pearson, and Halpert (13, 26)

reported cases resections of the involved lobes have been performed, it seems to us that any procedure, short of total removal of the involved lung, is irrational. Only by complete excision of the entire lung can the primary focus be adequately removed, and lobectomy does not permit removal of the regional lymph nodes. The performance of simple lobectomy in carcinoma of the lung is just as illogical as partial removal of the breast in mammary carcinoma with no attempted extirpation of the regional lymph nodes. Another reason for total pneumonectomy is that approximately 75 per cent of pulmonary neoplasms originate in the proximal bronchi. As shown by Bonniot, Monod, and Evrard, it is not possible to apply a tourniquet high enough on the pedicle of the lung to permit division of the main bronchus without injuring the pericardium or other mediastinal structures. Moreover, from a technical standpoint, total pneumonectomy is a much more surgical and anatomical procedure than is lobectomy. The latter at best consists more or less of a makeshift operation. It is necessary almost invariably to cut through pulmonary tissue because of the incomplete division of the lung down to the hilum by the fissures which does not permit individual ligation of the bronchus and pulmonary vessels.

On the basis of our experience we are convinced that preliminary pneumothorax should be attempted in all cases of malignancies of the lung. This should be done preferably in stages, increasing the amount of intrapleural pressure

gradually until the pressure is definitely upon the positive side. Most surgeons agree that a preliminary pneumothorax is desirable. The procedure was originally advocated by Kuemmel who performed the first pneumonectomy in November, 1910. Pre-operative pneumothorax is of diagnostic importance in determining the presence, extent, and location of adhesions, thus permitting the pre-operative planning of the operative procedure. In those cases in which extensive basal adhesions are present, a posterolateral approach is preferable to an anterior one, whereas, conversely, a patient with adhesions involving the apex can best be operated upon through an anterior approach. Another decided advantage of pre-operative pneumothorax is the gradual compression of the pulmonary capillary bed, giving the right heart a chance to compensate for the increased peripheral resistance in this area, rather than permitting a sudden cutting off of the blood to the involved lung at the time of the ligation of the pulmonary vessels. This is particularly true in elderly patients whose cardiac reserve is diminished, and in whom malignancies of the lung are likely to occur.

Rienhoff (46) advocates the pre-operative introduction of beef broth bouillon into the pleural cavity in order to produce a serofibrinous pleurisy, which he believes decreases the incidence of infection following the operation.

Patients with pulmonary carcinoma usually have an anemia because of the associated infection and loss of blood. In such instances pre-

Fig 2 The reserve cell is the parent cell of the culminated cylindrical and goblet cells and also possesses the qualities of its ancestor cells in that it may differentiate into any kind of epithelial cell that a primitive endodermal cell is capable of producing. Hence the carcinomas of the lung may be (1) reserve cell carcinoma (2) cylindrical cell carcinoma and (3) squamous-cell carcinoma. Modified after D. Aunoy, Pearson and Halpert (13, 6).

Fig 3 Reserve-cell carcinomas grow in solid masses composed of round, elongated (oat cell) or polygonal cells forming no particular structure. Usually there is a palisade arrangement of the peripheral cells. Modified after D. Aunoy, Pearson, and Halpert (13, 16).

mentioned, this is the ideal method of diagnostic proof. According to Jackson and Konzelmann, the incidence of correct diagnoses obtained broncho-copically is approximately 75 per cent. This is about the incidence of hilar tumors and indicates that those cases, which are close enough to the main stem bronchi to be visualized, can be diagnosed by the trained bronchoscopist. Difficulty is likely to be encountered in eparterial bronchus tumors because of their location and because of the acute angle which they form with the right stem bronchus. Visualization usually can be obtained in those cases; however, in which the neoplasm is near the orifice of the eparterial bronchus.

The presence of malignant cells in expectorated material can frequently be demonstrated microscopically. By this method of examination, Dudgeon found carcinoma cells in 60 per cent of patients in whom a diagnosis of pulmonary neoplasm subsequently was proved. Similarly, the demonstration according to Mandelbaum's technique of malignant cells in the pleural fluid of those cases in which there has been extension to the pleura is of diagnostic importance. The latter is of little use early in the disease, however, because of the relatively late extension to the periphery, except in peripherally located lesions. The importance of this method of diagnosis lies principally in its prognostic value.

Thoracoscopic examination is another method of diagnosis in selected cases of pulmonary carcinoma and is particularly valuable in those cases with peripheral extension with or without pleural effusion. This method of examination is useful in determining the cause of the pleural effusion and the operability of the case. In those cases in which there is extensive seeding in the pleural

cavity, an attempt at radical extirpation is obviously not justified. In cases in which the lesion is located peripherally, obviating bronchoscopic visualization of the tumor, aspiration biopsy can be performed with relative safety and with a fair degree of accuracy. Martin and Ellis, in 1930, reported their results in a large series of aspiration biopsies done for a variety of conditions. In 2 pulmonary carcinomas microscopic diagnoses of the lesions were positive. Sharp reports 3 cases in which a positive microscopic diagnosis of pulmonary neoplasm was made on material obtained by aspiration. He believes that the method is particularly valuable in upper lobe malignancies. Binkle, reported a aspiration biopsies of the thorax performed in the Memorial Hospital. In 56 bronchogenic carcinomas a positive diagnosis was made by aspiration biopsy in 60 per cent, whereas bronchoscopic examination gave a positive diagnosis in only 43 per cent of this group. An accurate diagnosis is possible following aspiration biopsy only if the examining pathologist is capable of interpreting the changes occurring in the few cells obtained by this method, and if he is willing to commit himself on the basis of these findings.

TREATMENT

The treatment of carcinoma of the lung, as that of most carcinomas elsewhere, consists ideally of complete surgical extirpation. Surgical removal is particularly indicated in pulmonary malignancies because of the almost hopeless outlook following other types of therapy. While in a number of

Fig 4 Cylindrical cell carcinomas are composed of cuboidal or columnar cells forming acinar, tubular, or papillary structures. reported cases resections of the involved lobes have been performed, it seems to us that any procedure, short of total removal of the involved lung, is irrational. Only by complete excision of the entire lung can the primary focus be adequately removed, and lobectomy does not permit removal of the regional lymph nodes. The performance of simple lobectomy in carcinoma of the lung is just as illogical as partial removal of the breast in mammary carcinoma with no attempted extirpation of the regional lymph nodes. Another reason for total pneumonectomy is that approximately 75 per cent of pulmonary neoplasms originate in the proximal bronchi. As shown by Bonniot, Monod, and Evrard, it is not possible to apply a tourniquet high enough on the pedicle of the lung to permit division of the main bronchus without injuring the pericardium or other mediastinal structures. Moreover, from a technical standpoint, total pneumonectomy is a much more surgical and anatomical procedure than is lobectomy. The latter at best consists more or less of a makeshift operation. It is necessary almost invariably to cut through pulmonary tissue because of the incomplete division of the lung down to the hilum by the fissures which does not permit individual ligation of the bronchus and pulmonary vessels.

On the basis of our experience we are convinced that preliminary pneumothorax should be attempted in all cases of malignancies of the lung. This should be done preferably in stages, increasing the amount of intrapleural pressure

gradually until the pressure is definitely upon the positive side. Most surgeons agree that a preliminary pneumothorax is desirable. The procedure was originally advocated by Kuemmel who performed the first pneumonectomy in November, 1910. Pre-operative pneumothorax is of diagnostic importance in determining the presence, extent, and location of adhesions, thus permitting the pre-operative planning of the operative procedure. In those cases in which extensive basal adhesions are present, a posterolateral approach is preferable to an anterior one, whereas, conversely, a patient with adhesions involving the apex can best be operated upon through an anterior approach. Another decided advantage of pre-operative pneumothorax is the gradual compression of the pulmonary capillary bed, giving the right heart a chance to compensate for the increased peripheral resistance in this area, rather than permitting a sudden cutting off of the blood to the involved lung at the time of the ligation of the pulmonary vessels. This is particularly true in elderly patients whose cardiac reserve is diminished, and in whom malignancies of the lung are likely to occur.

Rienhoff (46) advocates the pre-operative introduction of beef broth bouillon into the pleural cavity in order to produce a serofibrinous pleurisy, which he believes decreases the incidence of infection following the operation.

Patients with pulmonary carcinoma usually have an anemia because of the associated infection and loss of blood. In such instances pre-

operative unmodified blood transfusions are desirable. It is also imperative that two or more donors be available at the time of operation, because prolonged bleeding may follow division of extensive adhesions and because of possible accidental massive hemorrhage in which the administration of blood during the operation is frequently life saving.

Anesthesia. Although pneumonectomy may be performed under local and spinal analgesia the latter being particularly popular in Canada and England we prefer cyclopropane inhalation anesthesia. Because of the wide opening in the chest wall it is necessary that the anesthetic be administered under positive pressure. All of our earlier cases were done under positive pressure intratracheal tubes being used, but we now are convinced and agree with Rienhoff (46) that the use of the intratracheal tube is deleterious, because of the likelihood of the introduction of infection and the increased secretion resulting from trauma which in the presence of a single lung following pneumonectomy, is particularly dangerous. One of our fatalities 14 hours after operation undoubtedly was due to trauma of the trachea by the intratracheal tube, resulting in such excessive secretion that the patient virtually drowned in her own secretions despite almost continuous aspiration (Case 5).

In those cases in which the pleural cavity is free, containing no adhesions the anterior approach advocated by Rienhoff (47, 48) is very satisfactory. Instead of the intercostal incision suggested by Rienhoff we are of the opinion that resection of the third rib from the lateral border of the sternum to the anterior axillary line is preferable (Figs 8-9). This gives a better exposure and permits a more satisfactory closure because it facilitates accurate approximation without tension of the pleura and intercostal muscles. The anterior approach is also applicable to those cases in which the lesion is located in the periphery of the upper lobe, and in which there are adhesions between the upper lobe and the parietal pleura. This approach however is not recommended for those patients in whom there are adhesions between the lower lobe and the posterior parietal pleura, because of the great difficulty encountered in mobilizing the lung. In such cases resection of the fifth rib through the incision suggested by Crafoord has been more satisfactory in our hands (Figs 10, 11-1).

A distinct advantage of the latter approach in addition to permitting the division of adhesions between the lower lobe and the lateral and posterior parietal pleuras under direct vision is that

the hilum can be approached from behind, thus allowing initial mobilization of the relatively fixed bronchus. Following division of the bronchus, which normally holds the hilar structures quite rigidly, dissection of the other hilar structures the pulmonary artery and veins, is greatly facilitated (Fig 13). In the posterior approach also, rib resection is preferable to intercostal incision. After the pleural cavity is opened and the lung is mobilized by division of adhesions by sharp dissection the hilum is exposed in the mediastinum by incising the mediastinal pleura anteriorly and superiorly in the anterior approach and posteriorly and superiorly in the posterior approach (Fig 14). The flap of mediastinal pleura thus formed is mobilized, thus exposing the hilar structures. The mobilization is greatly facilitated by the use of long ball tipped slightly curved scissors (Fig 14). The pulmonary artery, pulmonary veins, and bronchus are isolated individually (Fig 15).

Mass ligation of the hilum is to be condemned as an unsurgical procedure and one which will give bad results in the majority of cases because of the incomplete extirpation. It does not permit removal of the mediastinal lymph nodes in which metastases are likely to occur, and in many instances does not permit the complete removal of the tumor. This is particularly exemplified in our first case in which the tumor was located just beyond the bifurcation of the trachea in the left main stem bronchus. Although individual ligation of the hilar structures was performed the bronchus was divided insufficiently high to include the tumor. The pathologist who was present at the operation, noticed the absence of the tumor before the mediastinal wound was closed permitting further dissection of the bronchus up to the carina and the high removal of the bronchus and the adjacent wall of the trachea (Fig 16). The tumor was situated in the small segment of bronchus which was approximately 2 centimeters in length. The posterior approach is particularly applicable and desirable in those cases of right-sided malignancies because of the greater difficulty in approaching the hilum on this side due to the presence of the vena azygos extending over the eparterial bronchus. This is especially true in cases in which the lesion originates in the eparterial bronchus and in which extension to the mediastinum in this area is likely to be present. In 2 of our cases the inability to free the bronchus anteriorly necessitated ligation of the vena azygos. Subsequent slippage of the ligature resulted in fatal hemorrhage (Case 2). Through the posterior approach the vena azygos can be

Fig 6 Anteroposterior roentgenogram of chest of patient with carcinoma involving right lower lobe bronchus as characterized by slightly rounded but irregular shadow in lower right lung field adjacent to hilum. The mediastinum is displaced slightly toward the affected side (Case 3)

more easily and more safely ligated before the bronchus is isolated (Fig 13). Separate ligation of the pulmonary vessels is imperative, and is perfected by double transfixion sutures (Fig 17). The use of No. 2 silk, which is sufficiently strong to compress the vessels and not too large to interfere with the tying of the knot, is considered preferable to other suture materials. The bronchus is doubly clamped by means of crushing forceps and divided between the clamps (Fig 13). Before the bronchus is closed by means of interrupted No. 1 silk sutures, approximating the mucosal edges, the distal cartilaginous ring is removed from the end of the bronchus. The removal of all the mediastinal lymph nodes is an essential part of the operation and can be accomplished either through the anterior or the posterior approach. Obviously mass ligation of the hilar structures will not permit this.

Following the complete extirpation of all the mediastinal lymph nodes careful pleuralization of the mediastinum is imperative. The edges of the divided mediastinal pleura are approximated, and the stump of the ligated vessels and bronchus is covered with pleura (Fig 18). This is important to minimize the danger of infection and augment prompt healing of the bronchial stump.

In our cases we have not resorted to drainage, because we believe with Rienhoff (49) that filling of the pleural cavity with fibrinous exudate is important in the obliteration of the cavity. Ob-

Fig 7 Anteroposterior roentgenogram of chest of patient with carcinoma of right upper lobe bronchus which had extended peripherally to involve practically the entire lobe as confirmed by subsequent examination. The area of increased density, occupying nearly the whole upper lobe of the right lung, is produced by the peripheral extension of the tumor and not by atelectasis which would cause displacement of the mediastinum toward the affected side (Case 2)

literation of the cavity also is facilitated by elevation of the diaphragm which follows crushing of the phrenic nerve at the beginning of the operation. The thoracic wound is tightly closed, using interrupted No. 1 silk sutures for the pleura and the intercostal muscles. The superficial muscles and the skin are closely approximated by means of the same material. A compression sea sponge bandage is applied over the wound to obliterate the dead space and to lend support to the wound.

ANALYSES OF CASES

There have been 79 reported cases of total pneumonectomy for neoplastic disease. In addition to this number, the authors have performed total pneumonectomy for malignant disease of the lung in 7 cases making a total of 86 cases¹ (Table I, Graph 1). Of the 86 collected cases, including those of the authors, 55 (63.9 per cent) died and 31 (36 per cent) recovered. Of the 31

¹ Since this presentation 2 more patients have been operated upon. One, a male, age 56 years, had carcinoma of lower left bronchus. Pneumonectomy of left lung was performed November 17, 1938. Patient made uneventful recovery. The second patient was a white female with a metastatic melanoma of left main stem bronchus having its origin from a melanoma of right eye removed 23 years previously. Pneumonectomy of left lung was done October 12, 1938. Patient died 12 days after operation of uremia. Thus of total series of 9 cases 3 have recovered and 6 have died, giving a total mortality of 66 per cent.

Graph 1. Graphic representation of total mortality in 51 collected cases of pneumonectomy for neoplastic disease including 7 performed by the authors

Graph 3. Graphic representation of sex incidence in 51 collected cases of pneumonectomy including authors

Graph 2. Graphic representation of age incidence according to decades in 51 collected cases of pneumonectomy including authors

patients who recovered there were 5, or 5.8 per cent of the entire group of 86, who subsequently died either of metastases or of other causes. In 50 the age of the patient was stated. Two (4 per cent) were in the first decade of life, the younger being $3\frac{1}{2}$ years of age with a lymphosarcoma; 2 (4 per cent) in the second decade; 3 (6 per cent) in the third decade; 7 (14 per cent) in the fourth decade; 18 (36 per cent) were in the fifth decade; 14 (28 per cent) in the sixth decade; and 4 (8 per cent) in the seventh decade (Graph 2). Of the 50, 32 (64 per cent) occurred in the fifth and sixth decades. Of significance also is the fact that 14 (28 per cent) were younger than forty years of age.

The sex was stated in 51 cases including the authors' cases, of which 36 (70.5 per cent) were males and 15 (29.4 per cent) were females (Graph 3).

The localization as regards the side involved was stated in 53 cases. The left side was involved in

29 (54.7 per cent) and the right in 24 (45.2 per cent) (Graph 4). In 31 cases, including all of the authors', individual ligation of the hilar structures was done. Of this group 11 (35.4 per cent) recovered and 20 (64.5 per cent) died. Of 17 cases in which mass ligation was done and so stated, 4 (23.5 per cent) recovered and 13 (64 per cent) died. If we included in the fatal group having mass ligation 1 of the patients recovering who subsequently died of metastases, and in whom death may have been the result of incomplete removal of the lung, these respective figures would be 17.6 per cent and 82.3 per cent (Graph 5). This difference in the mortality percentage in the two techniques of treatment of the hilar structures demonstrates the superiority of individual ligation of the bronchus and pulmonary vessels combined with extirpation of the mediastinal lymph nodes.

Graph 4 Graphic representation of localization, according to side involved, of pulmonary neoplasms in 53 collected cases of pneumonectomy including authors'

Graph 5 Graphic representation of mortality in 48 collected cases of pneumonectomy including authors', according to treatment of hilar structures

Graph 6 Graphic representation of cause of death in 38 collected cases of pneumonectomy including authors'

In 38 collected cases, including the authors' series, death as a result of the operation was due to the following: 6 (15.7 per cent) hemorrhage, 8 (21 per cent) cardiac failure, 19 (50 per cent) infection, 2 (5.2 per cent of the total) late hemorrhage as a result of the infection, 3 (7.8 per cent) thrombosis and embolism, 1 (2.6 per cent) asphyxia, and 1 (2.6 per cent) peritonitis (Graph 6).

The type of neoplasm was stated in 66 cases including the authors'. Fifty-nine (89.3 per cent) were carcinoma, 4 (6 per cent) were primary sarcoma, 2 (3 per cent) were metastatic lesions,

(1, a metastatic sarcoma from a primary focus in the uterus, and 1, a melanoma in which the primary lesion had previously been removed. It was the surgeon's opinion in the latter case that the lung extirpation had resulted in recovery) In 1 (1.5 per cent) the lesion was found to be benign (Graph 7)

It has been the authors' experience that a total pneumonectomy on the right side is technically more difficult than that on the left, due principally to the fact that on the right side the vena azygos crosses over the eparterial bronchus, usually making the mobilization of the right main-

The sex was stated in 51 cases including the authors' cases of which 36 (70.5 per cent) were males and 15 (29.4 per cent) were females (Graph 3).

The localization as regards the side involved was stated in 53 cases. The left side was involved in

29 (54.7 per cent) and the right in 24 (45.2 per cent) (Graph 4). In 31 cases, including all of the authors', individual ligation of the hilar structures was done. Of this group 11 (35.4 per cent) recovered, and 20 (64.5 per cent) died. Of 17 cases in which mass ligation was done and so stated, 4 (23.5 per cent) recovered and 13 (76.4 per cent) died. If we included in the fatal group having mass ligation 1 of the patients recovering who subsequently died of metastases, and in whom death may have been the result of incomplete removal of the lung, these respective figures would be 17.6 per cent and 8.3 per cent (Graph 5). This difference in the mortality percentage in the two techniques of treatment of the hilar structures demonstrates the superiority of individual ligation of the bronchus and pulmonary vessels combined with extirpation of the mediastinal lymph nodes.

Fig 10 Drawing showing position of patient in posterior approach for pneumonectomy

there was electrocardiographic evidence of considerable myocardial damage. During the first 4 postoperative days his convalescence was very satisfactory. On the fifth day the pulse became irregular but slow, and about 10 hours after this developed the patient died. Postmortem examination revealed no other cause of death, except myocarditis (Case 6). One patient died of peritonitis from rupture of the intestine as a result of gangrene complicating a periarteritis nodosa of the mesenteric vessels 10 days after operation. The pulmonary wound was well healed, and there was no evidence of any disturbance in the chest (Case 3). One patient is living $2\frac{1}{2}$ years after operation (Case 1). The remaining patient survived the operation but the operation was done so recently that it is too soon to draw any conclusions concerning the outcome (Case 7).

Fig 12 Drawing showing method of elevating angle of scapula so as to expose the fifth rib along its entire length. The fifth rib is subperiosteally resected throughout its entire length and the pleura is opened by incising in the furrow left by the rib.

Fig 11 Drawing illustrating skin incision in posterior approach for pneumonectomy as devised by Crafoord. The incision begins over the fourth rib about 7 to 8 centimeters from the posterior midline, is extended downward beneath the angle of the scapula, and then up toward the midaxillary line to the level of the fifth rib which is followed anteriorly to the costal cartilage.

Fig 13 Drawing showing relation of hilar structures and steps of operation in posterior approach for pneumonectomy. The hilar structures are exposed by incising mediastinal pleura posteriorly and superiorly. The azygos vein is first exposed, doubly transfixed and ligated, and then divided between these ligatures. This permits easy access to the bronchus which is doubly clamped by means of crushing forceps and divided between the clamps. Following division of bronchus, which normally holds the hilar structures quite rigidly, dissection of the other hilar structures, the pulmonary artery and veins, is greatly facilitated.

Graph 7 Graphic representation of type of neoplasm in 66 collected cases of pneumonectomy including authors

Graph 8 Graphic representation of mortality in 53 collected cases of pneumonectomy including authors according to side of operation

stem bronchus difficult. This is borne out by the results obtained in right and left sided lesions in the collected cases including the authors. Of 24 patients with right sided lesions, 6 (25 per cent) recovered, and 18 (75 per cent) died. Of 29 patients who were afflicted with left sided lesions, 12 (41.3 per cent) recovered and 17 (58.6 per cent) died (Graph 8).

Of the authors' 7 cases, 5 died and 2 recovered, giving a mortality rate of 71.4 per cent and a recovery incidence of 28.5 per cent. Of the 5 fatal cases, 1 died on the table of hemorrhage as a result of slippage of the ligature from the vena azygos shortly after it was applied. In this case there was infiltration of the mediastinum in the region of the vena azygos, the tumor extending from the eparterial bronchus (Case 2). One died of asphyxia about an hour after the completion of the operation because of the tongue dropping back

before the patient had sufficiently recovered from the anesthetic (Case 4). One patient died as a result of severe tracheitis and pulmonary edema in the opposite lung which, in the authors' opinion was the result of trauma to the trachea by the intratracheal tube (Case 5). One died of cardiac failure 5 days after the operation. Pre-operatively

Fig. 8 Drawing illustrating site of skin incision over third rib from chondrosternal junction to anterior axillary line in anterior approach for pneumonectomy

Fig. 9 Drawing illustrating anterior approach for pneumonectomy. The third rib is resected subperiosteally from chondrosternal junction to anterior axillary line. Incision of the pleura is made in the bed of the third rib. Inset shows exposure and immediate ligation of internal mammary vessels.

SUMMARY

1 Primary pulmonary carcinoma is an important clinical entity because of its frequent occurrence. It occurs in approximately 1 to 2 per cent of all autopsies and from 10 to 15 per cent of all carcinomas.

2 Chronic irritation of the bronchial mucosa is probably the most important etiological factor. Repeated inhalation of smoke over long periods of time is believed to be a prominent, irritative factor.

3 All pulmonary carcinomas probably originate in the bronchial mucosa. A classification

based upon the embryological derivation of the tumor cell is presented.

4 Persistent cough with expectoration and hemoptysis, and thoracic discomfort are the most prominent symptoms and when present in a person past 40 years of age should always be considered as due to pulmonary neoplasm until proved otherwise.

5 Roentgenographic examination is particularly valuable in peripherally located lesions with parenchymal infiltration and in centrally located lesions with bronchial obstruction. Because most bronchial malignancies occur in the primary bronchi, bronchoscopy is especially valuable as a diagnostic procedure.

6 Treatment of pulmonary malignancy consists of total extirpation of the involved lung and removal of the mediastinal lymph nodes. Lobectomy and mass ligation of the hilar structures are condemned because they do not permit complete eradication of the lesion. Preliminary pneumothorax always should be attempted. Depending upon the location of the lesion, the presence and extent of adhesions, either the anterior or posterior approach with rib resection should be used in the treatment of these patients.

7 An analysis of 79 collected and 7 personal cases of total pneumonectomy for neoplastic disease is presented.

Fig 16 Diagrammatic illustration of futility of mass ligation and necessity of high section of bronchus as exemplified in authors first case. Although individual ligation of hilar structures was done the bronchus was divided insufficiently high to include the tumor. The pathologist who was present at the operation observed absence of tumor before mediastinal wound was closed, permitting further dissection of bronchus up to carina and high removal of bronchus to include tumor.

EVALUATION OF OVARIAN STERILIZATION FOR BREAST CANCER

GRANTLEY WALDER TAYLOR, M D, F A C S, Boston, Massachusetts

IN June, 1935, Dresser reported our experience at the Collis P Huntington Memorial and Pondville State Hospitals with ovarian radiation in cases of carcinoma of the breast with bone metastases. Following the policies he reported, we have continued to carry out artificial menopause in recurrent and inoperable cases at these hospitals, and in addition have offered and employed the procedure prophylactically after radical mastectomy in young women. Thus we are able to present briefly an additional series of 50 cases of therapeutic artificial menopause in which patients were treated between January, 1935, and April, 1937.

THERAPEUTIC ARTIFICIAL MENOPAUSE

These patients varied greatly on admission in the extent and stage of the disease. Many were advanced, untreated cases; others presented lesions otherwise operable in whom x ray examination detected early metastatic involvement; still others represented recurrent disease locally or metastatically, after radical or subradical surgery. It is difficult to reduce such a group to a common basis for analysis. Twenty patients showed possible or probable benefit from the procedure. In many cases, when the focus of disease could be radiated, the regression may have been due in part to the local radiation rather than to the menopause. This applies particularly to recurrent nodules in the operative area or to supraclavicular lymph node metastases in which local radiation is found to be particularly effective.

Among the 20 patients with probable or possible benefit, 9 patients showed regression of bone metastases of greater or lesser extent ranging from complete regression and recalcification to a change from osteoclastic to osteoblastic bone lesions. Six patients with recurrence in the operative area or supraclavicular area showed marked improvement, but again it must be emphasized that these cases also had the benefit of intensive local x ray therapy. One patient with pleural effusion and another with ascites were relieved

of the necessity of frequent paracenteses. There was apparent regression of pulmonary metastases in 1 instance. Finally, in 2 patients with rather widespread involvement, the progress of the disease seemed to be definitely arrested, in 1 patient for several months and in the other for a period of about 2 years.

Of the entire group of 50 cases, 42 patients are dead, 1 remains untraced and 7 are still living without evident active progress of the disease.

CASE REPORTS

CASE 1. No 10707. The patient aged 43 years had a radical mastectomy performed in October 1933. She was admitted in April 1936 bedridden with generalized skeletal metastases. Artificial menopause was employed in May 1936. Reports by letter dated November 1937 state that she is up and about, driving an automobile, doing house work and feeling better than she has in years.

CASE 2. No 10130. This patient who was 50 years of age had a radical mastectomy performed in June 1932. The axillary nodes were involved. There was a supraclavicular node recurrence in November 1935 when artificial menopause and local x ray treatment were employed. In January 1938 no evidence of active disease was seen but there was paralysis of the left vocal cord.

CASE 3. No 56132. The patient aged 37 years had carcinoma of the breast and axilla with cranial metastases. Radium implantation to breast and axilla was applied in May 1933; artificial menopause was employed in October 1933 and complete regeneration of cranium was observed in March 1935. New cranial metastases involving orbit occurred in May 1937. Her condition was unchanged but there were no further symptoms in October 1937.

CASE 4. No 4950. The patient 42 years of age had a radical mastectomy performed in December 1932. The axilla was not involved. She received postoperative x ray therapy. In December 1934 there was a recurrence in lung and mediastinum. Probably spontaneous menopause had occurred in 1933. She received pelvic radiation in February 1935 and in June 1938 there was no evident disease. Chest x ray was unchanged and there was no indication of radiation fibrosis.

CASE 5. No 35-949. The patient aged 35 years had a simple mastectomy performed in May 1935. There was a recurrence in the scar in August 1935 and local x ray treatment was used. Artificial menopause was employed in December 1935. In February 1936 there was a local recurrence plus axillary nodes for which local x ray treatment was applied. Menstruation returned in October 1936 when she received additional x ray treatment to pelvis. In March 1938 there was no evidence of disease.

CASE 6. No 33-1540. Biopsy was performed in 1929 upon the patient 34 years of age and radical mastectomy followed 2 weeks later. There were local recurrences in April, 1933 which were excised. Multiple skin nodules axillary and supraclavicular metastases appeared in December 1933 and she received local x ray therapy. Arti-

From the Collis P Huntington Memorial and Pondville State Hospitals.

Presented in the Symposium on Cancer before the Clinical Congress of the American College of Surgeons, New York, October 17-21, 1937.

TABLE I —AXILLARY INVOLVEMENT ON ADMISSION

Axilla not involved	23	43
Axilla involved	77	57

ficial menopause was employed in April, 1934. There was no evidence of disease in August, 1938.

CASE 7. M. C., aged 33 years, had a radical mastectomy performed in April, 1927. The axillary nodes were involved. Pleural metastases appeared in 1933 and there were recurrences in the scar tissue in 1934. Local x-ray therapy was applied with multiple thoracenteses. Artificial menopause was employed in 1935, and further thoracenteses were unnecessary. In August, 1938, she was troubled with cough and dyspnea, but x-ray findings were unchanged. There was some question of pulmonary fibrosis.

It is of interest to compare the present group with other published series of cases. Dresser found benefit in about a third of his cases. Ahlborn reported that about 70 per cent of his cases were improved, but he made no attempt to rule out the benefit attributable to local radiation therapy. Most of the scattered individual case reports record benefit to patients with bone metastases. Regression of pulmonary or visceral metastases are rarer, although Dresser reported a case of regression of pulmonary metastases. Skin and scalp nodules have disappeared in some cases, even when no local therapy is employed. The regression noted by earlier advocates of surgical menopause, Schinzinger, Beatson, Thomson, Lett, and others, was limited to the demonstrable superficial lesions. The authors also reported improvement in about one third of the cases subjected to castration. We are unaware of any cases of regression of liver or brain metastases. Inflammatory carcinoma does not often show notable benefit following artificial menopause (10).

Many of the patients, who are to benefit by the procedure, experience a marked improvement in their sense of well-being. Often they gain in weight and appetite, simultaneously with the arrest in progress of the disease. This general improvement occurs in favorable cases in spite of the existence of the menopausal symptoms which, in these patients, are often particularly troublesome.

We may conclude that as a therapeutic procedure, artificial menopause is of definite palliative benefit to about one-third of the patients with inoperable or recurrent carcinoma of the breast. The most striking and, in most instances, the most durable results are evident in the group suffering from osseous metastases. While ade-

Chart 1. Carcinoma of the breast, Massachusetts General Hospital, 1921-1929, survival after operation, cases with axillary involvement.

quate data are lacking, it is probable that life is prolonged in many of the patients. It is unlikely that patients with visceral metastases benefit very often from the procedure. We have observed no such encouraging cases, as those reported by Clarkson and Barker, in which apparent cure resulted from artificial menopause combined with intensive local x-ray therapy. In general it is fair to say that the benefit is transitory and capricious, although the occasionally gratifying results and the virtually negligible inconvenience would seem to justify the procedure in young women who are suffering from incurable disease.

PROPHYLACTIC ARTIFICIAL MENOPAUSE

Encouraged by the results in recurrent and inoperable disease, we have employed artificial menopause as a prophylactic procedure in young women following radical mastectomy for operable carcinoma of the breast. Forty-seven of these cases are available for study, of which 14 patients had no axillary node metastases, while 33 presented positive axillary nodes. Of the early and favorable cases 1 patient died of liver and cerebral metastases, and the 13 remaining are living, apparently free from disease for an average

TABLE II —PATHOLOGICAL GRADE OF MALIGNANCY

	Age Under 46 Per cent	Over 60 Per cent
No. of cases	146	156
Grade I	7	16
Grade II	49	56
Grade III	44	28

period of 2.8 years after operation. Of the 33 patients with axillary involvement 15 are dead, 3 are living with probable recurrence and 15 are living without evidence of disease for an average period of 2.7 years after operation.

Obviously it is premature to attempt any appraisal of the value of artificial menopause in this group. Accurate knowledge of the expected results must be available in a comparable group of radical operations in young women without artificial menopause. Such a study was carried out and reported in 1936 (11), in which 5 year end results in a group of young women were contrasted with results in older women. Briefly it was demonstrated that carcinoma of the breast tends to metastasize earlier in young women than that it tends to be of higher grade of malignancy and that postoperative recurrence takes place a little more promptly. These findings are pre-

sented in Tables I and II and Chart 1. As a result of the study it was concluded that in carcinomas of the breast of equivalent extent and of equal grade of malignancy age alone does not affect curability (Table III).

Reverting to Chart 1, it can be seen that the curve of survivals of both age groups is close to 50 per cent at the end of 30 months after operation. This corresponds to the figure for our artificial menopause group with axillary metastases at an average interval of 2.7 years after operation. Obviously, the curve for the artificial menopause group may flatten out hereafter, although from the chart it can be seen again that from this point onward the young and old groups run parallel courses. Hence it may be concluded that we have thus far observed nothing in our study to warrant the conclusion that artificial menopause is likely to be of striking benefit as a prophylactic procedure against recurrence after radical mastectomy.

We turn to the laboratories and hormonal studies for an explanation of the benefits which do take place in some of the recurrent cases. Studies of estrin and prolactin A, or the follicle stimulating hormone levels in carcinoma of the breast cases show no significant differences from levels in control individuals. The effect of artificial menopause on these levels is illustrated in Charts 2, 3 and 4 (7).

Chart 3 Successful radiation menopause Solid line urinary estrin excretion in international units dotted line urinary prolactin A excretion in mouse units

TABLE III — CURES WITH RADICAL OPERATIONS

Cases	Age	
	Under 45	Over 45
	117	113
	Per cent	Per cent
Cures	34	44
Axilla not involved	71	67
Axilla involved	20	21

Chart 4 Unsuccessful radiation menopause Solid line urinary estrin excretion in international units, dotted line urinary prolactin A excretion in mouse units

Note that in the case of oophorectomy (Chart 2), the estrin level falls at once to a low level where it remains. This is accompanied by a rapid rise in the prolactin A excretion, accompanied by hot flashes. The successful radiation menopause (Chart 3), shows similar curves, although the response is not so prompt. In the case of inadequate radiation (Chart 4), note that the estrin does not fall to the low menopausal level, but that it shows marked irregularities. Resumption of menses is heralded by a marked rise in the level of estrin and by a sharp drop in prolactin A.

Are we justified in assuming that the benefits observed in certain of the cases are due to the low estrin level obtained, either directly or through the compensatory response of the anterior pituitary hormones? Are we concerned with the effect of estrin on the calcium metabolism in accounting for the regressions of bone metastases? These are questions which cannot be answered authoritatively on the basis of available knowledge. It seems, in these cases which show favorable response to menopause, as if the tumor growth is unusually dependent on the presence of considerable amounts of estrin, and that removal of this growth stimulus temporarily results in retardation or actual regression in the disease.

The experimental work of Lacassagne, Loeb, his co-workers, and others, prepares us to accept the etiological significance of estrin in carcinoma of the breast. As far as we are aware, none of the experimental work justifies the assumption that growth of the tumor is dependent on a continuance of estrin stimulation after the development of malignancy has once taken place. If this assumption be correct, it seems unnecessary to point out that the menopausal symptoms, which

may take place, should not be treated by the administration of estrin.

We turn to the pathologists in vain for a definition of characteristics of the growth which would indicate a likelihood of favorable response. Until they can do so, we must continue to give the possible advantage to all cases of recurrent and inoperable disease, with the reasonable hope that a certain number of the patients will benefit as a result.

CONCLUSIONS

Artificial menopause may be expected to result in temporary regressions or improvement in about one-third of the cases with recurrent and inoperable carcinoma of the breast. The most striking benefit appears to accrue in cases with osseous metastases.

Artificial menopause cannot be demonstrated as advantageous when employed as a prophylactic procedure in patients who are submitted to radical operation.

Hormone studies are thus far unable to explain why the favorable effects take place; and pathological studies are unable to predict which cases will react favorably.

PALLIATIVE IRRADIATION OF METASTATIC TUMORS IN THE LUNGS

ALEXANDER BRUNSCHWIG, M D , F A C S , and ANNA HAMANN, M D , Chicago, Illinois

THE rather limited literature on irradiation therapy of pulmonary metastases has been reviewed recently by Treves. This author also cites 38 cases from the Memorial Hospital, New York, of pulmonary metastases from breast carcinoma, which were treated by irradiation, and compares them with 21 similar cases that did not receive such treatment. The average duration of life after treatment was 11.4 months whereas in the untreated cases it was 35.9 months. While isolated instances of improvement following irradiation therapy are admitted, the general conclusion is, that with rare exceptions, roentgenotherapy is of doubtful value in controlling mammary cancer which has invaded the lung.

This report includes the results obtained by irradiation of pulmonary metastases from various types of primary growths outside the thorax observed in 13 cases of the University of Chicago Clinics. These are summarized in the accompanying table.

In every case there was histological verification of the nature of the primary tumor. The diagnosis of metastatic pulmonary lesions was based upon roentgenographic appearances of the chest and in every instance, except in Case 5, the lesions were discrete, rounded masses and not diffuse shadows which are always more questionable. Necropsy was obtained in the majority of patients who died confirming the roentgenographic diagnosis.

Additional reports, not included in Treves' review, are those of Hohlfelder of a patient with pulmonary metastases from thyroid carcinoma who survived 8 years, Schulte reports a case of pulmonary metastases from Ewing sarcoma which regressed completely from the roentgenographic standpoint following irradiation, the patient dying 2 years later of sarcomatosis, and Fussl reports a case of thyroid carcinoma metastases which regressed after irradiation and the patient survived $4\frac{1}{2}$ years.

From the Department of Surgery and the Division of Roentgenology of the Department of Medicine, University of Chicago Clinics.

Presented in the Symposium on Cancer, before the Clinical Congress of the American College of Surgeons, New York, October 17-21, 1938.

Case number 523 in the Bone Sarcoma Registry is a white female presenting an advanced sarcoma of the left ilium in 1922, which was treated by irradiation. In the same year roentgenographic evidence of advanced metastases in both lungs was observed and the chest irradiated. The metastases disappeared and when last seen in 1938, 16 years later, the lungs were clear and there was no evidence of active disease.

ANALYSIS OF SERIES

In the series of 13 cases shown in Table I, complete, immediate regression of the metastases from the roentgenographic standpoint was observed in 9 instances. Five of these 9 patients died in 3 months to 1 year of carcinomatosis including recurrences in the lungs. Of the 4 patients remaining, 3 are alive 19 months, 21 months, and 7 years respectively, without roentgenographic evidence of active neoplasm in the lungs, and 1 died 18 months after treatment of an intercurrent complication, but at necropsy no evidence of malignant tumor was present at the site of metastasis, that is, in the mediastinum.

Dosage. Experience has shown that pulmonary metastases often exhibit a marked degree of radiosensitivity, even greater apparently than the primary growth. The explanation for this of course remains obscure but some of the factors may be vascularity and difference in "soil." The calculated tumor doses, employed in the series here reported, vary widely, and it is interesting to note that the small to moderate doses were as effective as the large doses.

Technique. The technique employed was as follows: 200 kilovolts, 5 to 1 millimeter of copper, plus 1 millimeter of aluminum filtration 5 to 25 milliamperes, 50 to 80 centimeters FSD, 10 by 10 centimeter to 20 by 20 centimeter ports on the anterior and posterior chest walls depending on number and size of lesions. Only the affected lungs were treated; the whole chest was exposed only when the metastatic lesions were bilateral.

No attempt is made to include all cases of pulmonary metastases treated, and to arrive at some mathematical expression of the probability of regression or prolonged survival following treat-

Fig 1 Roentgenograms of chest showing extensive pulmonary metastases from embryonal carcinoma of testis before October 1, 1934 and November 23, 1938 after x ray

therapy. Patient died 4 months later of generalized metastases but the case illustrates the phenomenal regressions that sometimes obtain in very radiosensitive tumors.

Fig 2 Roentgenograms of chest of patient with Ewing sarcoma of the pelvis and large pulmonary metastasis in right lung. The primary lesion was treated by means of irradiation and 6 months later when these roentgenograms

were taken the metastatic lesion was similarly treated and this therapy was followed by complete regression. The patient is free from evidence of active disease 24 months later.

Fig 3 Roentgenograms of chest of patient with Ewing sarcoma of pelvis and solitary metastatic mass in right lung. The primary lesion was treated by means of irradiation as was the pulmonary lesion 6 months later. There was

complete regression of the pulmonary lesion following treatment, and 21 months later the patient remained free from evidence of active disease.

Fig 4 Roentgenogram taken October 28, 1931, shows rounded mass in lower left lung, characteristic of a metastatic growth. One year previously the right leg was amputated for sarcoma of the lower femur. Following irradiation therapy to the pulmonary lesion there was

complete regression. The roentgenogram taken April 9, 1936, shows no evidence of metastatic lesions and the patient is at present well and clinically free from active disease 7 years later.

TABLE I—RESULTS OF IRRADIATION THERAPY ON 13 PATIENTS WITH PULMONARY METASTASIS

Patient age sex Hospital No	Primary lesion	Roentgen graph of chest	X-ray therapy calculated effective tumor dose	Immediate results (roentgenograph appearance)	Subsequent clinical course
1 G F 37 ♂ 100534	Embryonal carcinoma of testis	Large rounded masses in both lungs	2400 r in 307 days total to both lungs	Complete regression of masses in both lungs	Died 4 mos later of generalized metastatic tumor nodules in lungs at necropsy
2 R A 25 ♂ 110667	Embryonal carcinoma of testis	Large rounded masses in upper lobes of both lungs	1600 r in 173 days total to both upper lobes	Complete regression of masses in both lungs	Subsequently died of period of survival unknown
3 W K 4 ♂	Embryonal carcinoma of testis	Large rounded masses in upper mediastinum	1000 r in 36 days	Complete regression of mass	Died 15 mos later of metastatic tumor of mediastinal tumor
4 L C 5 ♂ 701	Carcinoma of kidney	Large rounded masses at medioposterior right lung	1500 r in 9 days	Complete regression of mass	Died of generalized metastasis 8 mos later
5 M L 31 ♀ 974	Carcinoma of breast	Moderate sized masses in right lung	3150 r in 4 mos	Partial regression of metastases	Died 2 yr later of carcinoma
6 H A 31 ♀ 97454	Carcinoma of breast	Multiple rounded masses in both lungs	2000 r to each lung in 5 mos	Marked regression of metastatic masses	Died of carcinoma 8 mos later
7 C N 50 ♀ 120705	Carcinoma of breast	Multiple rounded masses in both lungs	1050 r in 6 mos to whole chest	Marked regression of metastatic masses	Alive 13 mos later—clinical improvement
8 G P 44 ♂ 104715	Hypernephroma of kidney	Round masses in lower portion of left lung	1600 r in 2 days	Marked regression of metastatic masses	Clinically much improved 2 mos later
9 H P 41 ♂ 15455	Round cell sarcoma (fibrosarcoma)	Multiple rounded masses at base of right lung	1000 r in 10 days	Complete regression of masses	Recurrent metastatic masses in both lungs and sarcomatous 4 mos later
10 H C 10 ♂ 8357	Ewing's carcinoma of pelvis (primary lesion treated by x-ray)	Simple rounded mass in lower portion of right lung	700 r in 7 days	Complete regression of mass	Clinically free from active disease 22 mos later
11 S E 21 ♂ 150135	Ewing's carcinoma of pelvis (primary lesion treated by x-ray)	Large mass at mid portion of right lung	1500 r in 9 days	Complete regression of mass	Clinically free from active disease 24 mos later
12 M B 46 ♀ 27350	Fibrosarcoma of lower extremity (amputated)	Small rounded masses at mid portion of left lung	800 r in 4 mos	Complete regression of mass	Well 7 yrs later
13 C F 6 ♂ 150507	Carcinoma of right breast	Multiple rounded masses in left lung	160 r in 60 days	Complete regression of masses	Lived 1 yr died of carcinoma

ADDENDUM TO TABLE

CA 83. Patient developed recurrent fibrosarcoma of the transverse colon which was irradiated field of external reoperation metastatic mass treated at same time as mediastinal lesion (see report by Brunschwig and Fox)

CA 85. Patient developed bronchopulmonary carcinoma complicating metastases in lungs. Thus irradiated patient lived several months in fair condition. She also had skeletal metastases

CASE 6. Patient received x-ray therapy to treat for intracranial metastases producing severe symptoms (brain tumor). A 2400 r x-ray therapy to liver hepatic mass, while receiving therapy to lungs. During period of palliation the patient died almost a small metastatic site

CASE 7. Extensive skeletal metastases caused severe pain also irradiated with x-ray. It is believed that the patient died of metastatic disease

CASE 11. Roentgenograms of chest taken at interval of 16 weeks before irradiation was given to lung showed no apparent increase in size of metastatic mass. This fact does not indicate that the lesion observed was something other than a metastatic growth since pulmonary metastases have been observed to appear stationary for long periods. The nature of a lesion has been verified by necropsy. (See report by Fox et al.)

ment in any series of patients. This would hardly be possible in view of the very marked variation in the clinical picture presented by each case such as the general condition, site and number of metastases elsewhere than in the lungs, type of neoplasm, age, etc. While this series of patients is not an especially selected one it does not include an equal number of patients with extensive pulmonary and other metastases who were also treated but with no appreciable results.

The purpose of this report is to demonstrate that immediate marked or apparent complete regression of pulmonary metastases in roentgenograms of the chest may not infrequently follow

irradiation therapy and that this is occurred in the above series is accompanied by a varying degree of palliation of local and general symptoms for a brief or a more prolonged period. The argument that such treatment may entail eventual tissue damage and augment the general depression resulting from anemia, etc., would not appear to be a serious contra-indication to such treatment since small to moderate doses have in this series proved effective and measures may be adopted to combat anemia which such doses might induce.

It is not intended to carry the impression that irradiation therapy of pulmonary metastases offers a means to alter noticeably the course of the advanced stage of malignancy as found in large numbers of patients. It is believed, however, that such a procedure, when followed judiciously, offers a possibility of palliation in certain individual cases, especially when the general condition of the patient is not bad at the time such metastases are first observed.

CONCLUSION

Moderate irradiation of pulmonary metastases from malignant tumors is indicated as an attempt at palliation in cases in which evidence of such

metastases is first discovered, and in cases in which the general condition of the patient is at least fair.

THE SURGICAL TREATMENT OF CARCINOMA OF THE LARYNX

GORDON B. NEW, M.D. F.A.C.S. Rochester, Minnesota

SURGICAL intervention has proved to be the most efficient method of treating patients with carcinoma of the larynx. The surgeon, however, in order to give all patients with this disease the best that can be offered and taking into consideration those who are poor surgical risks and inoperable cases must be able to employ not only pure, surgical procedures but, in addition, surgical diathermy, radon seeds inserted under suspension laryngoscopy, and external irradiation.

DIAGNOSIS

Growths in the supraglottic region may produce few, if any, symptoms until they are large, so that growths of the epiglottis are frequently overlooked. The patient may have an undetermined pain or ache in the throat with little difficulty in swallowing, and the growth particularly if it be situated on the posterior surface of the epiglottis may evade inspection unless a careful examination is made. Until these growths have extended into the larynx hoarseness is not produced.

Growths of the glottis cause hoarseness as an early symptom so that adult patients who are hoarse over a period of a month should have a careful examination to make sure that the hoarseness is not due to a malignant lesion. It is generally thought that malignant tumors of the larynx usually occur in men. While this is true one sees many malignant tumors of the larynx in women in whom a thyrotomy and, in some cases, a laryngectomy is necessary.

Age should not be a factor in deciding the likelihood of a malignant tumor as the ages of the patients at The Mayo Clinic on whom it has been necessary to perform laryngectomy ranged from 16 to 77 years. In the uncertain case preliminary biopsy is always advisable, the patient and his relatives understanding the surgical procedure that should follow the positive histological diagnosis. I do not think it advisable to perform a larynx in a possibly malignant laryngeal lesion unless treatment is to follow immediately.

From the Section on Laryngology, Oral and Plastic Surgery, The Mayo Clinic.
Presented in the Symposium on Cancer before the Clinical Congress of the American College of Surgeons, New York, October 17-21, 1938.

After excluding the usual conditions considered in differential diagnosis of malignant tumor of the larynx, that is tuberculosis, syphilis, benign tumors and granulomas of contact ulcers and some of the more unusual lesions, there remains a group of patients with pathological conditions of the larynx in which it is impossible to make a definite clinical diagnosis. In this group of patients exposing the larynx by means of suspension laryngoscopy is a valuable aid, not only in the diagnosis but also in the treatment of many of these laryngeal lesions. Many larynges, presenting thickening caused by inflammation, thickened leucoplasias, areas of epithelial hyperplasia and other so called precancerous lesions are better visualized by binocular examination as obtained under suspension laryngoscopy. This type of laryngoscopy is used with intratracheal gas and ether anesthesia and allows of an excellent exposure of the larynx. In this way an accurate biopsy may be obtained.

In cases in which histological examination of the fresh frozen section proves the condition to be a benign one such as leucoplacia, epithelial hyperplasia caused by inflammation or a very small early epithelioma, the lesion may be destroyed under suspension laryngoscopy with a long protected surgical diathermy point. Before diathermy is used the etherization of the patient is discontinued and he is allowed to take several deep breaths. The anesthesia is then continued with nitrous oxide only. In those cases in which benign lesions and early epitheliomas are removed endoscopically by surgical diathermy, careful surgical judgment must be used in selection of patients. In elderly patients and patients that are bad surgical risks, the results show that this method of removal can be used with much less danger and with a good prognosis in selected cases. In the cases in which the lesion is more extensive, suspension laryngoscopy allows of a thorough examination and a decision may be made at the time as to whether a thyrotomy and exploration or a laryngectomy should be done.

METHODS OF SURGICAL REMOVAL

Surgical procedures including removal and surgical diathermy are the most effective methods

Fig 1 The mucous membrane flap, indicated by long arrow, that is dissected from the posterior wall of the cricoid cartilage, indicated by short arrow, in cases in which the situation of the growth will permit

of treating carcinoma of the larynx. In addition to these, however, the use of radon seeds and external irradiation is of great value in many cases. It is the evaluation of the various methods of treatment and their application to the individual case that makes the most efficient method of treatment for malignant tumor in its various locations and types. In determining the best method of treatment, the duration of the history of hoarseness, the location of the lesion and its extent, the histological grade of the tumor, the question of metastasis, the patient's age and general condition as to surgical risk, must all be considered. These are all questions which play an important part in the surgeon's decision.

Carcinoma of the larynx may be divided into 3 groups: (1) the supraglottic growths, (2) the intralaryngeal growths, including the subglottic, and (3) laryngopharyngeal growths arising in the pyriform sinus or the postcricoid region. Many of these growths may involve one or possibly more of the regions but the smaller growths will come under this grouping. The type of carcinoma present may be determined by the appearance of the tumor and the microscopic grading. Unless the type of growth is such that it can be cared for in a conservative way and the excision made well wide of the growth, a more extensive operative procedure should be employed. The work of New and Fletcher on the selection of treatment for carcinoma of the larynx brought out the fact that the low-grade tumor could be removed with a much narrower margin than the more active growths.

Fig 2 Closure of the pharynx with two rows of chromic catgut sutures in the shape of a T

The patient's age and general condition are very important factors in determining the treatment. Patients more than 75 years of age or those with poor general conditions, such as bronchiectasis, diabetes, or angina, are subject to added surgical risks and while they may withstand a major surgical procedure, a less radical one is advisable sometimes under the circumstances. It is in these elderly patients that a two stage operation, of which the first is a preliminary tracheotomy, is of great value. In some of these, too, the use of suspension laryngoscopy and removal of the growth perorally is advisable, and in some external irradiation only is employed. In many cases it is necessary to do a thyrotomy as an exploratory operation before the particular surgical procedure to be employed can be decided on. While conservation of the voice must be considered whenever possible, the eradication of the disease is of the first importance.

Supraglottic growths Tumors of the epiglottis are usually of a low grade of malignancy. However, tumors of the base of the tongue of a high grade of malignancy may involve the epiglottis. In growths in which the lesion is limited to the epiglottis, removal with surgical diathermy under suspension laryngoscopy gives excellent results. Even in cases in which the growth involves the base of the tongue, it may be thoroughly removed with diathermy and radon seeds can be inserted into the involved area. To illustrate how extensive destruction may be accomplished by this method, in 1 case I removed the inner surface of the hyoid bone as a sequestrum. The patient, who had an extensive squamous-cell epithelioma,

Fig 3 Tying of the sutures at the extremities of the horizontal portion of the T in this way burying the upper portion of the wound

grade 4 on a basis of 1 to 4, was well at the time of this writing which is more than 5 years after operation

In the supraglottic tumors in which the aryepiglottic fold is involved, pharyngotomy through the thyrohyoid membrane or lateral pharyngotomy is the treatment of choice. In this way a wide exposure can be made and as radical an excision performed as is necessary. At times a window may be removed from the thyroid cartilage on the opposite side to the growth, or the thyroid cartilage divided allowing an excellent exposure through which the growth may be destroyed with surgical diathermy. A transmandibular and translingual exposure as used by Trotter to remove epiglottic growths, is technically an excellent operative procedure, but I feel that other methods are far more efficient and that they result in a much lower operative mortality.

Carcinoma of the epiglottis may fill almost the entire hypopharynx so that only a margin of the larynx is visible. There is a tendency for these low grade tumors to be more of an excrescence like a cauliflower that has gone to seed, than an invading growth. If the growth is an infiltrating one without limited margins, removal under suspension laryngoscopy should not be attempted. In some supraglottic growths which involve the aryepiglottic fold and the pyriform sinus, laryngectomy along with removal of a portion of the lateral wall of the pharynx is feasible. The type of operation and the technical procedure which are to be employed should be suited to the individual lesion.

Fig 4 Left the pharynx is closed with a second row of chromic catgut sutures. Silk sutures approximate the skin and tongue-shaped flap. A mattress suture which is carried through the anterior wall of the esophagus, closes the skin above the trachea. Right mattress sutures complete the closure of the skin above the trachea. The lateral Penrose cigarette drains and the iodoform gauze pack in the upper portion of the wound are not shown.

Intralaryngeal growths. Malignant lesions involving the inside of the larynx may be taken care of in several ways. Thyrotomy and exploration are advisable in many cases in which the exact limits of the lesion are undetermined and in which there is a question as to whether a conservative operation or a laryngectomy is advisable. Surgical diathermy is used in all cases in which thyrotomy is employed. The early lesion without fixation is widely removed and the base destroyed with diathermy. When the lesion is more advanced with possibly some limitation of movement involving the anterior two-thirds of the vocal cord, the growth is removed along with the cartilage and the base is destroyed with diathermy. This is really a hemilaryngectomy. In growths involving one vocal cord and the anterior commissure without fixation, or in which the anterior commissure is involved along with the anterior half of both vocal cords, the method suggested by Jackson for low grade tumors gives excellent results. One must remember however that frequently growths involving the anterior commissure may extend through the cricothyroid membrane, and also that in highly malignant growths one cannot get a wide enough margin unless the anterior portion of the thyroid cartilage is removed as well as the soft tissues. If a wide removal is made in this manner the patient may still have an airway and a passable voice. Larynx

gectomy is done in more extensive lesions in which, owing to the size, location, and type of the growth, a conservative removal, which allows of a sufficient margin of safety, cannot be performed.

When laryngectomy is done, I use paravertebral anesthesia and I prefer the midline incision. I then divide the hyoid bone and retract it laterally with rake retractors. The larynx is freed from the muscles, first on one side and then on the other. On account of the possible extension of the growth through the thyroid cartilage or the cricothyroid membrane, it is essential that this dissection be made very carefully. If there is any question of extrinsic involvement at this point, wide excision, either with a knife or with surgical diathermy, is advisable. The trachea is cut across below the growth and procaine is then injected into the posterior wall of the larynx and trachea. If the extent of the growth will permit, a tongue-like flap of mucous membrane and submucous tissue is dissected free from the posterior wall of the cricoid cartilage, leaving it attached to the tracheal mucous membrane (Fig 1). This aids in the closure of the skin to the trachea. It is necessary to inject some procaine into the pharynx after the trachea has been cut across, since it is difficult to block this area with paravertebral anesthesia.

Dissection is then carried up onto the posterior wall of the larynx. The pharynx is opened, and in cases in which there is some question as to the posterior extension of the growth, exploration is made with the finger at this time. The larynx is then removed. The opening into the pharynx in the shape of a T is closed with two layers of fine, chromic catgut sutures (Fig 2). The sutures at the extremity of the crosspiece of the T are left long and after the rest of the pharynx is closed are tied together, thus burying the central portion of the wound (Fig 3). The trachea is sutured to the skin by means of silk sutures. One mattress suture just above the trachea is carried through the anterior wall of the esophagus in order to bring it forward against the skin. Mattress sutures are used in closing the lower 5 centimeters of the skin above the trachea. Rubber Penrose cigarette drains are carried into the pockets on either side and an iodoform gauze pack is placed in the upper part of the wound. A No 7 tracheal tube is inserted and a dressing is applied over the upper part of the neck (Fig 4).

Little reaction follows operation by the procedure I have outlined if a preliminary tracheotomy has been made. The temperature usually does not go above 100 or 101 degrees F and after about 4 days goes back to normal. The drains

are removed gradually; they are usually out about the tenth day. In a large percentage of cases, the closure about the posterior wall of the trachea and lower 5 centimeters of the incision heals almost by primary intention. If, as frequently happens, a small pharyngeal fistula is left at the upper end of the incision, it is freshened up after the wound heals sufficiently and is closed with mattress sutures. The tracheal tube is usually removed about the fourth day and kept out the greater part of the time unless there is some tendency for the tracheal opening to close. In this way less reaction occurs about the upper end of the trachea. In regard to the question of removal of lymph nodes in these cases, I do not do a routine block dissection of the necks of patients who have a malignant lesion of the larynx without involvement of the nodes. In cases in which there is nodal involvement of low grade, I feel that the lymph nodes should be removed. To illustrate the value of neck dissection, 1 patient with squamous-cell epithelioma, grade 2 of the cervical lymph nodes, lived for 18 years after operation and died of adenocarcinoma of the stomach.

Laryngopharyngeal growths Postcricoid growths are practically always squamous-cell epithelioma, grade 4, but may be of low grade and, as a rule, are found in women. A lymph node is usually palpable at the time of the first examination. Trotter's method of doing a transthyroid pharyngotomy is the treatment of choice if there is no involvement of the lymph nodes and the patient is otherwise a good surgical risk. However, the prognosis in these highly malignant tumors in this region is such that, unless the operation is done early, surgical intervention offers little except in a limited group of cases. Tumors of the pyriform sinus are usually squamous-cell epithelioma, grade 3 or 4, and usually metastasize early.

It is in these two groups of cases, involving the postcricoid region and the pyriform sinus, that external irradiation has accomplished a great deal and in my opinion it should be the treatment of choice. I have had 2 such patients that have been greatly benefited by irradiation.

One was a man, 45 years of age, with the growth involving the arytenoid and postcricoid regions, a squamous-cell epithelioma, grade 3, causing laryngeal obstruction. I performed a tracheotomy and then followed this with roentgen therapy in small fractional doses. The tumor disappeared entirely and the patient has been well with no recurrence 18 months later. The second patient was a man, aged 55 years, with a growth in the pyriform sinus, grade 2, with 2 midcervical lymph nodes that felt malignant. After roentgen therapy the enlargement of the nodes disappeared as well as the local lesion and the patient has been well nearly 2 years.

Neither of these patients would have been benefited by surgical intervention whereas roentgen therapy has obtained an apparent cure. These, however, are only 2 of the many patients who have been treated but they do tend to show that in certain cases the use of irradiation is well worth while.

Quick stated that the present status of irradiation therapy renders total laryngectomy obsolete, that an early malignant tumor is as favorable for irradiation as for surgical extirpation and that the ultimate results are better. He did not, however, present sufficient evidence to back up such sweeping statements. The end results in surgical treatment of malignant lesions of the larynx are well known. The operative mortality rate is less than 3 per cent and the end results show that

between 50 and 60 per cent of patients requiring laryngectomy are alive 5 years later. Good speech may be obtained in most patients on whom thyrotomy has been performed by the good vocal cord approximating a scarred band. In patients for whom laryngectomy has been necessary the use of the pharyngeal muscles or an artificial larynx frequently produces much better speech than the pre-operative voice.

The selection of treatment in carcinoma of the larynx requires keen surgical judgment. The laryngologist, who wishes to give efficient treatment to all patients, must use, as they seem indicated, all of the various methods that the medical profession has at its disposal. The problem is to evaluate and apply them efficiently to each individual patient.

X-RAY TREATMENT OF INOPERABLE CARCINOMA OF THE LARYNX

HENRI COUTARD, M D., Chicago, Illinois

CLINICALLY and histologically there exist 2 main varieties of laryngeal cancer: cancer composed of undifferentiated cells, and cancer composed of differentiated cells. The former live in a loose vasculo-connective tissue which is itself undifferentiated and disorganized. In this tumor bed the neoplastic cells multiply rapidly, at the same time respecting the highly differentiated tissues such as nerves, blood vessels, and muscles. They are in contact by the lymphatic spaces with the lymphatic vessels, and they have a tendency to early and widespread dissemination in the loose vasculoconnective tissue. They are accompanied by early regional adenopathy whose evolution is irregular, sometimes rapid and sometimes stationary, or even regressive when they originate from the vestibule or the ventricular cavity. This type of cancer generally arises in regions which for many years have been the site of acute inflammatory changes, the inflammatory processes having induced certain modifications.

The differentiated variety of cancer cells lives in a dense and highly organized vasculoconnective tissue bed, and sometimes in the muscle itself, for which it has a special affinity. At first these cells infiltrate the intermuscular spaces, afterward penetrating the muscle fibers and causing an early immobilization of the underlying muscle. In regions where they grow the lymphatics and blood vessels are destroyed, the nerves are compressed and the nerve sheaths are infiltrated. Cancers with differentiated cells have no tendency to distant dissemination. They develop slowly and penetrate the lymphatic and vascular tissue later. They are generally of limited extent and of small size. Regional adenopathy is rare. When it occurs, its development is irregular and slowly progressive. These cells appear in a region in which a chronic inflammatory state has led to a special modification in the dense connective tissue.

CHOICE OF TREATMENT

These facts explain why the undifferentiated cancers composed of cells which are young, wan-

From the Chicago Tumor Institute

Presented in the Symposium on Cancer, before the Clinical Congress of the American College of Surgeons, New York, October 17-21, 1935

dering, and highly fragile in the presence of external agents, disappear promptly under the influence of radiation regardless of their size, whereas, cancers composed of differentiated cells, which exhibit more mature evolution without great movability and remain close to their source of origin, behave differently.

The tendency of differentiated cells to live together in a group and to be intimately associated with muscle distinguishes them from undifferentiated cells which conserve their complete independence in relation to the tumor bed in which they live. Muscle infiltration is a peculiar and characteristic feature of differentiated cells which results not only in the muscle becoming rapidly immobilized but also in an intimate association of the neoplastic cells and muscle fibers which it is impossible to separate. In this process the neoplastic cells appear to receive their nourishment from the muscle fibers which slowly lose their biological properties, leading to a replacement of the muscle fibers by fibrosclerotic tissue. Under these circumstances the disappearance of differentiated neoplastic cells under the influence of radiation is almost impossible.

If one succeeds in sterilizing a lesion of this type by means of x-rays, a result which is very rare, there always develops a necrotic destruction of the treated area either immediately or after 3 months, 6 months, or 1 year. Examples of this type of lesion are highly differentiated and infiltrating cancers of the vocal cord, differentiated cancers of the anterosuperior part of the tongue, and cancers of the anterior part of the pillar, which are composed of differentiated cells. Sterilization of the tumor with conservation of the tissues of the tumor bed under these conditions is not possible. The union of the neoplastic cells and surrounding normal cells has been too intimate. Necrosis of the anterosuperior portion of the tongue following sterilization of the epithelioma is of no great significance, but necrosis of the tissues occupied by the neoplasm at the level of the larynx, even with complete disappearance of the cancer, always results in death if there has not been a previous tracheotomy, and sometimes provokes bronchopneumonia even with a previous tracheotomy. The elimination of the necrotic

portion, which may be soft or cartilaginous, requires too great an effort on the part of the tissues and organism and is sometimes prolonged for as much as 2 years before elimination and repair are complete. The treatment of differentiated cancer of the larynx which infiltrates and immobilizes the underlying muscle belongs, therefore, to the domain of surgery rather than to that of radiology.

In summary, differentiated cancers of the larynx which are technically operable belong to the domain of surgery if the hemilarynx is completely fixed. It is only when the immobilization is incomplete that this type of cancer can be cured by irradiation.

Cancers composed of undifferentiated cells are easily modified by radiation regardless of whether they are small or large, operable or inoperable. This variety of cancer is best treated by radiation. In this type, regardless of the degree of development the invaded parts remain slightly movable and the lesion disappears without apparent modification of the connective tissue in which it has developed. Because of their tendency to cellular dissemination, the undifferentiated cancers are never biologically operable even though they are technically operable. Surgical intervention increases the danger of dissemination. We might emphasize the danger of surgical intervention in this type even when the surgical procedure is adequate by demonstrating a large number of cancers of the larynx, pharynx, oral cavity, and breast, but we think that these facts are already so well known that this is not necessary.

METHOD OF ROENTGEN THERAPY

Following are the methods of x ray treatment in brief, for it is a subject which is only of limited interest.

Cellulicidal technique—radio epithelitis, radio epidermite. The treatments which have been used until now have had for their aim the destruction of neoplastic cells, that is to say a cellulicidal technique. After some days of treatment, the cells are covered by a false membrane when the cancer is composed of undifferentiated cells. Depending upon the degree of differentiation, these false membranes appear between the fifth and thirteenth days after the beginning of treatment. On the thirteenth day the false membrane appears on the normal mucous membranes (radio epithelitis). When a cancer is composed of cells which are more fragile than those of the normal epithelium of the mucous membrane the false neoplastic membrane appears before the false membrane of the normal mucous membrane. If the neoplastic cells do not show a false membrane

until the sixteenth or seventeenth day or later, it is because they are less sensitive than the normal cells of the mucous membrane. Under these conditions we are dealing with a cancer whose cells are more differentiated. If no cellular modification or diminution in size appears before the twenty fifth day, it is because the sensitivity of the cells is in the neighborhood of those of the cutaneous cells which are destroyed only between the twenty sixth and twenty eighth days (radio epidermite).

This information is valuable for cancers which are not infiltrating, that is to say, those which have respected the muscle. As soon as the cells have invaded the muscle, the cellulicidal method is, as we have already said, not effective because it is unable to yield any rational cure that is sterilization of the cancer with conservation of the normal tissues. Consequently, we shall discuss here only the cellulicidal technique as it is applied to undifferentiated or slightly differentiated cancers which have not infiltrated the underlying muscle. This technique may be applied in several ways.

Daily and continuous treatment. The roentgen therapy of cancer of the larynx gives us results only when we distribute in the larynx through two lateral fields 50 centimeters square, a total dose of 7,000 r that is, about 5,000 r to the side of the lesion and 2,000 r to the opposite side measured on the skin. This daily continuous treatment is distributed as follows: in 20 to 25 days for cancers composed of slightly differentiated cells, in 15 days at a maximum for cancers composed of very differentiated cells and in 40 days for cancers which are completely undifferentiated. There is a tendency now to reduce this time.

Preparatory treatment. If the cancer is very extensive and very infected and the general state of the patient is bad, we precede the main treatment by a preparation lasting for 13 to 26 days, without interruption between the two varieties of treatment. The fields are increased on the surface reaching 100 square centimeters and administered between 5 and 50 r according to the voltages and according to the thickness of the tissues. The aim of these irradiations is not to act on the neoplastic cells whose cellulicidal threshold never appears below a daily dose of 150 r, but to reduce the infection and to improve the connective vascular tissue. It is, therefore, necessary to diminish as much as possible the daily dose in order to avoid the development by the rays of fibrosclerotic connective tissue, a transformation which reduces the sensitivity of

the cells. This method was used for all the cancers of the larynx in 1932 and seems to us to be the cause of improvement in 5 year results.

Periodic treatment We have also studied the effects of periodic treatment in the differentiated forms of cancer. Non-continuous treatment in 2 or 3 periods, distributed in such a manner that the moment of cellucidal effect coincides with the moment of sensitivity of the normal epithelium of the mucous membrane, which appears on the thirteenth, twenty-sixth or thirty-ninth days. This coincidence is possible only if the daily dose largely surpasses the cellucidal threshold of the differentiated neoplastic cells, which is rarely less than 400 r. This treatment constitutes the only method which has given us any results for cancer of differentiated cells.

Palliative treatment In cases not successfully treated by radiation, as for example in the case of a recurrence, and in cases in which it is impossible to administer efficacious treatment by radiation on account of marked cachexia, all varieties of treatment known as palliative treatment simulate the type of treatment which has been described as *preparatory*, but with still weaker daily doses, or 5 to 25 r, and with an aim only to modify favorably the vasculoconnective tissue.

ASSOCIATION OF SURGERY AND ROENTGEN THERAPY

The combination of surgery and x-rays in the treatment of inoperable cancer of the larynx has not yielded any better results than those obtained by surgery alone or by x-rays alone. In the treatment of postoperative recurrence, non-sterilization after x-ray therapy is often associated with necrosis at the site of the operative scar. This necrosis has sometimes resulted in a large fistulous tract extending from the larynx into the skin. On the other hand, when a surgical operation is performed upon a recurrence following irradiation, radionecrosis of the soft parts and cartilage is frequently produced.

These complications are due largely to the fact that the combination of irradiation and surgery is utilized as a result of urgent necessity rather than a careful and deliberate study of the problem before treatment is instituted.

Let us consider two groups of cases in which the association of these two therapeutic agents is carefully studied before treatment is begun.

1 In the management of differentiated carcinomas which infiltrate the muscle and which are inoperable without being too extensive, it is sometimes useful, after tracheotomy, to perform an intentionally incomplete operation in order to

conserve the greater part of the larynx. This operation, the aim of which is to remove the most radioresistant portions of the lesion, is followed as soon as possible by complete irradiation. This irradiation should be administered before there has been a chance for fibrosclerosis to develop. During the time immediately after operation, there exists a type of postoperative cellular activity which renders the tumor cells more radiosensitive. When this type of cancer, which is composed of differentiated cells, has destroyed the muscle and cartilage, the operation serves to eliminate the infected and necrotic tissues.

2 In the management of carcinomas composed of undifferentiated cells the following procedure is adopted. If one chooses to treat this form of cancer surgically, it is wise to precede the operation by comparatively small doses of x-rays, that is to say, 3000 r units administered in 10 to 12 days. A daily dose of 250 to 300 r units will suffice to cause the disappearance of the most fragile cells which are the most dangerous elements from the point of view of postoperative dissemination. The surgical operation should follow the irradiation by about 17 days at the latest after the first x-ray treatment.

For the reasons which have been discussed, it is necessary that the therapeutic procedures in both circumstances be grouped as closely as possible in order that the second treatment receive the greatest benefit from the first.

RESULTS

General results. As to patients treated in our service in the Curie Foundation in 1921 to 1932 for inoperable cancer of the larynx or for postoperative recurrence, out of a period of 12 years of treatment, 3 years only yielded good results. They are 1921, 1926, and 1932, with 50, 52, and 66 per cent 5 year survivals and free of disease. The other years are bad or mediocre. The general average for 5 year survivals is only 39 of 142 patients or 27 per cent. The study of all these cases has established that cancers composed of undifferentiated cells were very numerous in the 3 favorable years, and that cancers composed of differentiated cells were very numerous in the course of the bad years. This accounts in part for the inequality of the results, but in fact our inadequate knowledge of the effects of radiation on cancer, very dissimilar from the point of view of cellular differentiation, muscle invasion, invasion of cartilage, and musculocartilaginous necrosis, explains that our technique was sometimes efficacious and sometimes not. In an effort to correct the dissimilarity in results, we have

been obliged to test every kind of treatment. These changes in technique have sometimes appeared contradictory.

The factors just mentioned partly explain the results during a course of successive years. The best year, 1921, was followed by the worst year, 1922, since in the latter we did not have a single 5 year cure out of 11 patients treated.

Likewise, after 1926 we had a series of mediocre years. 14 and 16 per cent in 1929 and 1930, respectively, are the worst results after 1926. In 1931 there were 28 per cent. The results attain their maximum in 1932 after which the percentage will probably go down again.

During the course of these 12 years, the duration of treatment was sometimes long and sometimes short. The treatment periods have varied from 10 to 50 days; the daily dose between 200 r and 800 r measured on the skin; the fields between 40 and 150 centimeters square. In spite of these variations the total dose which caused the disappearance of cancer of the larynx remained in the neighborhood of 7000 r.

CRITICAL PERIOD AFTER FIVE YEAR SURVIVALS

Among the 8 patients treated in 1921, 4 reached the 5 year survival period without signs of cancer; they are still free of disease after 10 and 15 years.

The patients treated in 1926 and 1932 reached a 5 year survival in a higher proportion: that is 9 out of 17 or 52 per cent, and 6 out of 9 or 66 per cent, but the results after 5 years are inferior to those of 1921.

Among the 17 patients treated in 1926, of which 9 reached the 5 year period with freedom from symptoms, 4 subsequently died: 3 died of new cancerous manifestations of the larynx, 1 during the course of the sixth year and 2 during the course of the eighth year. The fourth patient died at the advanced age of 79 years during the course of the ninth year without apparent recurrence. Thus there are 3 deaths with new cancerous manifestations between the sixth and the eighth years, that is, 3 out of 9, or 33 per cent of the patients who survived 5 years. These manifestations appeared in the 3 cases at the end of the sixth year. The number of patients surviving without symptoms remains the same, 9 at 12 years after treatment.

Among the 9 patients treated in 1932, 6 have reached the 5 year period without symptoms. Of these 6, 2 have died during the course of the sixth year of new cancerous manifestations: 1 case was a postoperative recurrence.

In summary, of 15 patients remaining free of disease for 5 years, 5 or 33 per cent have developed

a new cancerous manifestation during the sixth year. Thus it seems that about the end of the sixth year, there appear special phenomena which are able to provoke the appearance of new cancerous manifestations.

Certainly the number of cases of cancer of the larynx observed is not large. We should not be permitted to speak of these facts if we had not seen similar phenomena in other locations. In our cases of cancer of the oral cavity and of the tonsil, in particular, when a patient presented a new cancerous manifestation death occurred between the sixth and eighth years. The new cancerous manifestations seem to begin about the end of the sixth year, and the patients who escape this manifestation remain without symptoms for 10 to 15 years.

In the treatment of undifferentiated carcinomas which are apparently cured, there seems to exist a critical period appearing about 6 years after the irradiation. This critical period causes death 1, 2, or 3 years later and if the patient escapes this critical period the cure appears to be definite.

The question arises as to whether this period is the same in other types of tumors. We are completely ignorant of this. Although we have observed this in adenocarcinoma of the breast composed of undifferentiated cells, still in general the number of these cases of 5 year survival is too small. The statistics of the Registry of Bone Sarcoma of the American College of Surgeons shows that of 112 cases of bone sarcoma living and clinically free of disease for a period of 5 years or more following treatment by surgery or by irradiation, 6 patients died of cancer after 5 years, of which 3 died of metastasis during the course of the eighth year.

ONE OF THE CAUSES OF THE APPEARANCE OF THE CRITICAL PERIOD

The changes in the methods of treatment which we have considered in their time as improvements did not always constitute real improvements or more precisely we now see the advantages and disadvantages of the different methods utilized.

This is especially true of the methods applied in 1926 and 1932, which have given us results that seem superior to those of 1921. This improvement in results was apparent and not real. Certainly the percentage of 5 year survival without symptoms has increased but this increase, as we have said, is compensated by the lowering of the duration of the survivals, since the results of 1926 and 1932 fall during the course of the critical period from 52 and 66 per cent to 35 and 44 per cent.

The disappearance of all the neoplastic cells in the cases of 5 year survivals has been obtained regardless of whether the treatments were long or short. However, when the daily doses have not reached a certain minimum threshold, particularly during the course of the last days of irradiation, the critical period has appeared; and this would suggest that after the disappearance of the neoplastic cells, special elements remained which were not modified by the treatment. We find the same effect in other locations

What are these special elements? Are they cellular? Are they composed of a special group of invisible mother cells, hidden in a sclerotic vasculoconnective tissue such as one sees in cancer of the breast in which new cancerous manifestations seem to appear at every period after 5 years? This is only remotely probable since the moment of the cancerous manifestations seems fixed, 6 years

On the contrary, are they formed of a substance having cellulomitogenic properties or a carcinogenic substance whose cancerization effect appears after 6 years? We should be obliged to admit it if the moment of the critical period were the same for all varieties of cancer.

Regardless of the theoretical considerations which these facts suggest, they bring to us for the moment useful indications for radiation technique which may permit us to escape the critical period and avoid recurrence. These facts teach us especially that for the same total dose we must reach a high threshold during the course of the final daily treatments, a threshold sometimes greater than 800 r. On the contrary, under certain conditions, daily doses of 5 r preceding the cellulocidal treatment appear efficacious by a process of which we are totally ignorant. This possibility of utilizing extreme variations in the

daily doses and in their effects in roentgen therapy is a fact not only very curious but encouraging for the future.

SUMMARY

Clinically and histologically there exist two main varieties of laryngeal cancer: cancers composed of undifferentiated cells having a great tendency to early and widespread dissemination in the loose vasculoconnective tissue, and cancer composed of differentiated cells having a special affinity for the muscles and an immobilization of muscle without any tendency to dissemination.

Cancers composed of undifferentiated cells are treated successfully and easily by x-rays. Because of their tendency to dissemination, they are not biologically operable, even though they are technically operable.

Cancers composed of differentiated cells are in the domain of surgery, and usually are not curable by radiation because of the intimate connection between muscle cells and carcinoma cells.

Treatment of inoperable cancers by x-rays which we have used are: (1) preparatory treatment, (2) daily and continuous treatment, and (3) periodic treatment.

The preparatory treatment has increased the number of 5 year survivals, but the insufficient daily doses during the last 3 days of treatment has provoked sometimes the appearance of a recurrence about 6 years after irradiation. This seems to be the critical period, and death occurs 1, 2 or 3 years later. If the patients escape this critical period, they are still free of disease after 15 years. The possibility of utilizing extreme variations in the daily doses, very small or 5 r in the preparatory treatment, and very high, or 900 r during the last day of the continuous treatment, is very encouraging for the future.

OBSTETRICS AND GYNECOLOGY

ESTROGENIC HORMONES AND CARCINOGENESIS

LUDWIG A. EMGE, M.D., San Francisco, California

AS far as is known, the highest cancer incidence in the mammalian world is found in mice. This is particularly true of mammary cancer which in certain strains, may affect 100 per cent of the females and, if they receive estrogen¹ artificially a high percentage of the males. Because of this latter occurrence, it has been concluded that estrogen possesses cancer provoking properties. It is the purpose of this paper to discuss certain pertinent factors and present further experimental studies regarding the relation of estrogen to neoplasia. The voluminous literature dealing with this subject has been reviewed recently by Taylor Jr and is therefore omitted here.

The fact that a substance manufactured in a mammalian body for the maintenance of normal functions can under certain circumstances, provoke cancer in an organ normally stimulated by it is unquestionably important and deserves careful consideration of its true significance. There can be no doubt that cancer of the breasts of mice, provided this tissue has been hereditarily destined to develop cancer, is dependent on the presence of estrogen (18). Comparative studies indicate that the factor of prime importance in this mechanism is not so much *estrogen* as it is *hereditary susceptibility*. Mice, as mentioned show a particularly high tendency to mammary cancer. Rats on the other hand, possess an equally great immunity to this form of cancer although they are subject to mammary adenofibromas which have shown malignant potentialities in transplantation (5, 13, 14). This evident difference in species susceptibility strongly suggests that the rôle of estrogen in carcinogenesis is limited by certain biological patterns.

The huge mass of information on carcinogenesis which has been accumulating for a period

of years indicates that cancer is not a single disease but a group of diseases the common aspect of which is the destruction of life. More and more evidence is forthcoming to show that the provocative causes vary with different types of cancer and probably vary in their specificity in different species. On purely experimental evidence it is possible to divide these causes into two or possibly three groups (Fig. 1). One produces neoplasia at the site of first contact such as tar, benzantracene derivatives and certain parasites and is therefore truly *carcinogenic*. The other incites distant cells to assume a malignant behavior without necessarily producing neoplasia at the site of application which might be called *carcinotropic*. Estrogen and certain viruses possess this faculty. The third an undefinable factor may possess both faculties and would cover the still unexplained cancer provoking action of certain rays. Provocative factors are modified by age and sex and probably by vitamins and enzymes although this is not readily demonstrated. However, it has been shown that vitamin A deficiencies favor metaplasia according to McCullough and Dalldorf, and enzymes normally necessary for certain cell metabolism disappear with malignant degeneration.

Carcinogenic impulses are either favored or neutralized by a group of hereditary factors. General susceptibility or immunity to malignant neoplasia dominates all other hereditary factors such as species, strain, organ and cell differences which exert a modifying influence in a more specialized sense. Their importance is demonstrated in the oft cited classical experiment of Fibiger on gastric cancer in rats, which proved that it required a specific susceptible host, a specific transmitting vehicle, and a specific cancer provocative to produce cancer in a specific cell of a specific organ.

The mechanism of transmission of hereditary factors is still in dispute. Based on breeding experiments on mice Little considers this essentially a non Mendelian mechanism following maternal lines and indicating that the cytoplasm of the egg can transmit characteristics independent of

From the Department of Obstetrics and Gynecology, Stanford University School of Medicine.

Presented in the Symposium on Obstetrics and Gynecology before the Clinical Congress of the American College of Surgeons, New York, October 17-21, 1933.

¹The terms *estrogen* and *estrogenic* are used here for all substances having estrus-producing properties as suggested by the Council of Pharmacology and Chem. of the A. M. A. in Vol. 107, page 1221, 1936.

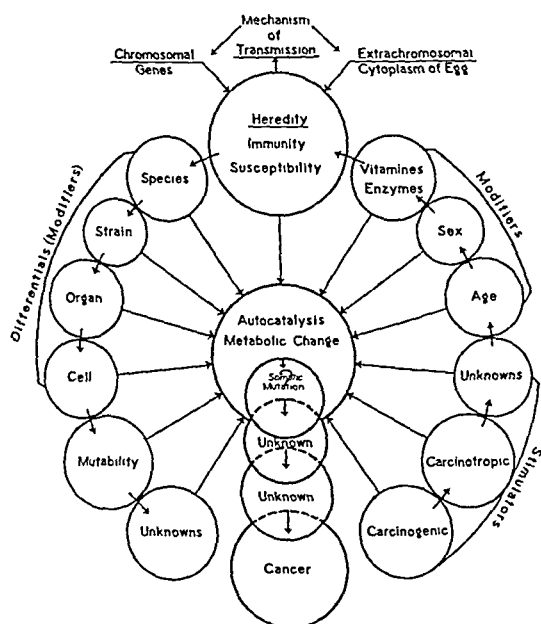

Fig 1 Causes of cancer

chromosomes. This is quite in opposition to Slye's deductions, which favor chromosomal transmission according to Mendelian laws.

The mutability of cells, i.e., the faculty to change either the physical or functional characteristics, is still an unknown factor. However, since tissues subject to frequent cyclic and

regenerative changes often exhibit unusual catalytic and metaplastic tendencies, mutability may be a factor in carcinogenesis. The existence of other factors not yet demonstrated is taken for granted and grouped under "unknowns." No attempt is made here to explain the mechanism which brings all factors together, which Loeb calls "autocatalysis," i.e., something that generates from within.

The action of estrogenic hormones in relation to mammary cancer in mice conforms remarkably well with the scheme just outlined. Briefly, these hormones incite distant cells (mammary) to undergo malignant degeneration *when hereditarily prepared*, and ordinarily do not produce neoplasia at the site of application. Age and sex modify their action in varying degrees according to Loeb (17), Cori, and Murray. When mammary tissue is not susceptible to cancer it responds to estrogenic stimuli by orderly proliferation which, although extensive, remains definitely limited by physiological capacity.

The secondary modifying factors show themselves in various ways. Thus, duct cells respond far more readily than acinar cells to the carcinotropic influence of estrogen. The importance of the organ differential is expressed by the failure of estrogen to precipitate a malignant reaction in other organs hereditarily destined to develop cancer. Strain differentials are shown by the complete lack of malignant response in breast tissue of certain strains of mice, and species differences are evident from comparative studies of

mice, rats, and rabbits. The results of certain experiments, attempting through superphysiological stimulation with estrogen to incite the epithelium of the genital tract to uncontrolled hyperplasia, further demonstrate the modifying action of differentials. In mice treated over periods of time with relatively large doses, Gardner Allen, Smith and Strong, and Suntzeff Burns, Moskop and Loeb observed occasional cancer like proliferations in the vagina and uterus in a few animals. Overholser and Allen observed a cancer like lesion on the cervix of 1 monkey in a group treated with theelin and local traumatization. Others (10, 15, 19, 20, 21), studying rats and monkeys under increased estrogen loads, obtained only metaplasias. The difference in end results probably is not due to variations in the estrogenic stimulation but rather to the result of variations in receptiveness of the genital tissues. Compared with mammary cancer the yield of genital cancer, even in susceptible mice, is in

significant. This is in line with the assumption that the relation of estrogen to tissue proliferation depends on biological patterns. The experiments of Perry and Gunzton point in the same direction. These investigators found that in mice of an unpedigreed stock and of unknown origin the combination of 1, 2, 5, 6 dibenzanthracene with theelin yielded a greater number of tumors than dibenzanthracene alone.

Assuming that tissue proliferation produced by estrogen conforms to hereditary biological patterns we have attempted for some time to determine this pattern in a strain of rats entirely refractory to cancer. This strain came originally from a Wistar strain of the University of Chicago, which had been bred at Stanford University since 1903, and studied in our laboratory since 1928. Breeding females occasionally produce a benign mammary adenofibroma readily transplantable but subject to sarcomatous degeneration (Emge, 5). Although we have transplanted these tumors for nearly 10 years, we have never encountered a carcinomatous degeneration. Since they respond to hormonal stimulation as well as normal breast tissue (Emge and Wulff, 9) it occurred to us that if we could maintain a constant state of lactation it might be possible to invite not only a progressive proliferation of the epithelium but an unusual storage of secretion which, according to Bogen, is a factor in mammary cancer in certain mice. In order to produce this state we destroyed the litters of breeding females implanted with mammary adenofibromas, at birth, and immediately bred them again. By this means it was possible to achieve an almost constant state of pregnancy resulting in immense hyperplasia of tumor and breast tissue (Emge and Murphy, 7). Although the storage of milk assumed relatively great proportions, particularly in the tumors no malignant changes

Fig 4

were observed. With the subsidence of the pregnant state, involution proceeded at a normal rate in the breasts but was considerably slower in the adenofibromas. Animals observed over long periods showed no latent changes in either tumors or breasts. This is not different from the behavior of adenofibromas of the human breast, which involute after lactation at a slower rate than the normal breast tissue. Failure to produce abnormal cell proliferation in adenofibromas storing massive quantities of secretion speaks against retention as a factor in carcinogenesis in this strain of rats.

Having failed to produce abnormal cell proliferation by unusually prolonged spontaneous stimulation, we (8) resorted to the administration of aqueous theelin. Doses approximating or exceeding ordinary physiological requirements were given over long periods to male and female

rats again implanted with mammary adenofibroma. The outstanding result was a fibrosis of the transplanted adenofibroma, a decrease in glandular components with an occasional hyperplasia of the ducts, and a slight proliferation of the same structures in the normal breast tissue *in situ*. We noticed that animals receiving twice the dosage of others produced slightly more epithelial proliferation in both tumor and normal breast epithelium. However, the difference did not warrant the conclusion that the action of the hormone was quantitative. In another experiment, smaller though physiologically excessive doses of theelin were given for longer periods, and we observed still more fibrosis in similar tumors and practically no changes in the normal breast tissue. However, in this experiment 1 tumor was found to have developed a tremendous cystic mastoplasia, which emphasizes the fact that

Fig 12 Endometrium after 28 000 international units of theelin in 32 days cystic hyperplasia

qualitative and quantitative differences to estrogen stimulation exist in morphologically similar tissues (Emge and Murphy, 6)

We are now investigating this question in a series of experiments, to be reported in detail at a later date. In the present study, rats 168 days old received 50 international units of aqueous theelin bi weekly for from 20 to 34 weeks. Breast changes were moderate with the usual slight proliferation of duct tissue, but the difference between 20 and 34 weeks of treatment was not very remarkable. In the genital tract however the response of all epitheliums was distinctly different for the 2 periods the longer treatment producing a more massive cornification of the squamous epithelium and a more definite increase in the size of the endometrial glands. Allowing for a possible difference in the effect of the time element on different organs the action of theelin was less quantitative on the breast tissue than on the genital tract.

In order to further clarify this point we are now observing the results of theelin in oil given in doses varying from 100 international units weekly to 1 000 international units daily to a

large group of female rats of different ages implanted with a very glandular adenofibroma. Breast tissue is being removed sufficiently often to obtain information about the progressive action of the hormone. The animals are disposed of at various periods of the experiment and their genital tracts studied *in toto*. We appreciate that the large doses employed are out of all proportion to physiological requirements and do not parallel therapeutic practice. However, having found previously that doses within physiological limits, regardless of the length of time of administration, did not create spectacular changes we felt that we should go the limit in dosage in order to learn if there was any dose which might incite malignant proliferation. We felt that by pushing the dosage we might have a better chance to ascertain limits of immediate response as a basis for quantitative differences. The state of this experiment justifies only the presentation of preliminary observation.

Doses of theelin as great as 1,000 international units daily produce definite physiological changes in our rats within 10 to 14 days. The weight gain stops abruptly as demonstrated in Figure 2 for young animals the hair of the older rats becomes

Fig 13

seedy and the tips of the hair turn brown. Soon the animals refuse to eat and would eventually die if we did not forestall this by selective destruction. Within each group of animals there are individual differences in tolerance, most marked in the older groups. We found that theelin has a lethal limit which, in older animals, approximates 60,000 to 70,000 international units in 64 to 71 days. Younger animals are more tolerant to large doses. Since the injection of oil alone, used as a vehicle for theelin, produces none of these reactions, it must be assumed that theelin alone is responsible. We presume that this is not a direct action of theelin but an indirect result of profound changes in the endocrine system, particularly marked in the pituitary and adrenal glands (3, 4, 28). This is well in line with weight disturbances and atrophy of the ovaries common in the animals studied by us. The hypophysis enlarges rapidly under the influence of large doses and ultimately goes on to adenomatous degeneration. Smaller doses will yield the same result if given sufficiently long as demonstrated in Figure 3. Zondek recently reported that the formation of pituitary adenomas in female rats required about 8 months

of treatment with fairly large doses of estrogen. We obtained the same result with larger doses in 70 days. This, again, speaks for quantitative differences in the action of estrogen.

The changes observed in the genital tract during estrogen stimulation also indicate a quantitative response. In 400 day old rats, one receiving 800 international units in 50 days (Fig 10) reacts much less drastically than 1 receiving 12,000 international units in 14 days (Fig 11), and even still less than 1 receiving 44,000 international units in 50 days (Fig 13). The degree of response of the genital epithelium, therefore, depends not only upon dosage but upon the frequency of administration. These changes in the cervix and vagina (Figs 4, 5, 6, 7, 8, 9) begin with a persistent cornification of the surface epithelium similar to estrus, but more pronounced. This is followed by increased activity and multiplication of cells resulting not only in a thickening of the surface epithelium but in a downward extension of epithelial columns. At the same time, the sharp demarcation between cervical and endometrial epithelium disappears and endometrial glands begin to proliferate. As the estrogen load

Fig 24

Fig 24 Adenofibroma after the administration of 29 000 international units of theelin in 34 days cystic hyperplasia

is increased, the stratified epithelium of the vagina and cervix becomes edematous and wide spread vacuolization takes place. The endometrium has by now progressed to a state of hyperplasia which suggests polyp formation. The glands are greatly dilated and filled with secretion. Metaplasia of the endometrium next occurs near the cervical junction. At first, only isthmic glands are affected, the endometrial glands having assumed a degree of dilatation very similar in appearance to that seen in functional hyperplasia of the endometrium in man (Figs 10, 11, 12). Progressive metaplasia of the entire epithelial lining of the uterus, which ultimately involves the endometrial glands, marks the height of the reaction (Fig 13). At this point the limit of physiological response is reached and cellular exhaustion is expressed by extensive shedding of the surface layer and the accumulation of polymorphonuclear leucocytes in the uterine cavity as well as in the glands (Figs 14, 15). Sterile pyometra invariably marks the end phase of the response of the genital tract in this strain of rats. It may be assumed therefore that in the absence of hereditary susceptibility to cancer the physiological pattern,

typical for the behavior of the genital tract of these rats determines the extent and severity of the cellular response beyond which no amount of stimulation will produce further hyper- or metaplasia. This mechanism would seem to be equally important as that responsible for mammary cancer in mice hereditarily destined to develop cancer.

The quantitative differences in response to estrogen are further demonstrated in a comparison of breast tissue *in situ* with implanted mammary adenofibroma removed at different periods of treatment. Here also a biological pattern seems to determine the ability of these tissues to respond to various estrogen loads although not as dramatically as in the genital tract. In both the normal (Figs 16, 17, 18, 19, 20, 21) and the tumor tissues (Figs 22, 23, 24, 25, 26), the height of the secretory response occurs at about 45 000 international units given in 45 days. The various stages of secretory response begin with a simple proliferation of the ducts followed by lobulation. Acini proliferate next and secretion appears. With further proliferation distention of alveoli and ducts, due to the accumulation of secretion becomes evident and cyst formation results. This

is more pronounced in the tumors (Fig 24) than in breasts *in situ* (Fig. 19), and is probably due to a greater storage of secretion. Cyst formation is followed by fibrosis, again more marked in the adenofibromas, which have a greater abundance of stroma (Figs 20, 25). Vacuolization of the glandular components precedes minor degrees of metaplasia, which marks the beginning of the end-phase of physiological response. In the breast tissue a slow breaking-down of glandular epithelium marks the lack of further proliferative ability. As far as we have been able to learn, the end-phase of secretory response in the adenofibromas is of a similar nature, but the limited tolerance of the host to large doses of theelin has not permitted us to determine this accurately. As yet, we have not encountered stromal or epithelial changes which would indicate that theelin in oil can incite malignant changes either in the normal breast tissue or in the implanted adenofibromas in this strain of rats. This, in a general way, corresponds with the behavior of the epithelium of the genital tract and confirms the assumption that estrogen, even in extreme doses in a breed of animals protected by an inherent immunity, does not incite malignancy in tissue it normally stimulates.

SUMMARY

In a series of experiments on white rats of different ages, in which the dosage of aqueous theelin and theelin in oil were administered in varying dosages and over varying periods of time, no malignant changes were produced in the mammary glands, in the genital tract, or in transplanted mammary adenofibromas. Since this strain of rats is entirely free from spontaneous cancer, it is assumed that a hereditary immunity protects breast and genital tissue against excessive and uncontrolled proliferation regardless of massive doses of estrogen. The proliferative changes observed are quantitative and self-limited, and probably do not occur spontaneously even under high physiological loads of estrogen, as observed in pregnancy experiments. A maximal response to estrogenic stimulation is terminated by a process of cell exhaustion and cell destruction, probably dependent upon changes in the hypophysis due to superphysiological stimulation by estrogen.

Evidence is accumulating to prove that the action of the estrogenic hormones is controlled by definite biological patterns, and that their cancer-provoking faculty in small laboratory animals is strictly limited by hereditary tendencies. There also is evidence that the effect of estrogen on mammary and genital epitheliums is essentially

quantitative. It is again emphasized that the tremendous dosage used in certain of these experiments does not parallel spontaneous physiological processes and far exceeds any clinical usage.

After 2 years of observation on the effects of estrogen stimulation of breast and genital tissue in a strain of white rats free from spontaneous cancer, we have come to believe that the carcinogenic effect of this hormone must be extremely limited. We are not convinced, because estrogen favors spontaneous mammary cancer in mice highly susceptible to this malignancy, that other species of mammalia are likewise affected.

This research has been supported in part by the Memorial Fund for Cancer Research and the Rockefeller Fluid Research Fund of Stanford University.

The theelin used in these experiments was generously donated by Parke, Davis and Co through the courtesy of Dr E A Sharp.

The assistance of Dr G L Laqueur, L M R Wulff, and Pierre Lassegues is gratefully acknowledged.

MULTIPLE PLASTIC OPERATIONS IN THE MANAGEMENT OF PROLAPSUS UTERI

EDWARD A. SCHUMANN, M D , F A C S , Philadelphia, Pennsylvania

PROLAPSE of the uterus is usually defined as a downward herniation of that organ and is said to be complete or incomplete according to whether the entire uterus protrudes from the vulva or only a portion appears. Most definitions go on to state that there is an associated elongation of the broad and uterosacral ligaments, with relaxation of the anterior vaginal wall and cystocele, together with relaxed and generally lacerated perineum.

These definitions do not sufficiently differentiate the various types of complete prolapse with respect to the nature of the associated lesions, a most important consideration from the surgical aspect, when one must decide what type of operation or operations will best meet the specific indications.

TYPES OF PROLAPSUS UTERI

The first type considered is prolapse in multiparous women, with relaxation and dilatation of the vagina but without either cystocele or definite laceration of the perineum. This variety of procidentia is not uncommon and has been especially observed among those women with a tendency to ptosis of the abdominal organs. While it is true that in these subjects the bladder does protrude, it is noteworthy that the greater the vesical distention the higher the bladder withdraws into the vagina. The apparent cystocele disappears from sight either wholly or in part. In this variety palpation of the perineum will disclose a fairly firm floor, the sulci uninjured, and the levators competent although more or less relaxed.

The second type is prolapse in multiparous women with marked laceration of both the anterior vaginal wall and the perineum. The cystocele increases in size as the bladder fills and there is a large thin walled rectocele (sometimes with enterocele) indicating profound injury to the muscles and fascia of the pelvic floor.

The third clinical variety is a compound of the first two types, i.e., prolapse with marked cystocele and a firm perineal floor, or the reverse. This compound type is fairly common and the writer

has often been impressed by the apparent integrity of the pelvic floor among women in whom complete procidentia was present with huge cystocele.

The fourth and rarest variety is prolapse of the small uterus of the nulliparous and sometimes virginal woman.

The cause of prolapsus uteri is generally conceded to lie in a stretching and loss of tone of the supports of the organ together with injury to the tissues forming the vaginal canal. With the support being lost, intra-abdominal pressure slowly forces the uterus downward.

The anatomy of the pelvic supporting structures is most complex and so many fasciæ and ligaments have been described that the whole subject has been rendered into a state of confusion. The matter has been condensed and simplified by Frank whose brief and practical summary will be used here. The pelvic organs are held in place by two sets of structures:

1. There is an upper or holding apparatus consisting of those fasciæ and masses of connective tissue occupying the subperitoneal space, i.e., the space between the peritoneum and the levator fascia. This space is entirely filled with connective tissue which may be loose and areolar, or thrown into firm fibromuscular and ligamentous bands. Passing through these masses of connective tissue are found the urethra and vesical neck, the vagina and the rectum, together with blood vessels, nerves and lymphatics. This mass of connective tissue falls into three principal divisions, all originating in the juncture of the cervix uteri with the lateral pelvic wall.

The name, "cardinal ligaments," has been applied to the most important of these divisions but the term is somewhat misleading because no definite ligaments can be demonstrated. The space between the supravaginal cervix and the lateral pelvic wall is filled with a dense mass of connective tissue, the fibers of which form bands of different length and thickness, radiating in a sort of fan shape from the pelvic wall to the cervix and which very firmly connect these structures to each other.

At a lower level similar bands attach the vaginal fornices to the pelvic wall, and higher up

Fig 1 The section passes just below the junction of sacrum and coccyx through the anterior superior spine of the ilium and the great scrotic notch 1 Rectum 2 peritoneum on lateral margin of cul-de-sac 3 connective tissue of the parametrium 4 obturator internus 5 ovary 6 iliopectus (Redrawn after Eycleshymer and Schoemaker *A Cross Section Anatomy*)

the connective tissue gradually thins and merges into the peritoneal folds of the lower aspect of the broad ligaments. These connective tissue masses, the so called cardinal ligaments, are the essential structures for holding the uterus in place and, so long as their fibers remain uninjured and unstretched, prolapse of the uterus is impossible no matter what other anatomical defect may be present.

Figures 1, 2, and 3 all represent cross sections of the female pelvis redrawn from *A Cross Section Anatomy* by Eycleshymer and Schoemaker. They illustrate admirably the extent of the connective tissue into which the cervix uteri and the vault of the vagina are set as it were, and the tremendous importance of these structures in the maintenance of the uterus in its normal station.

The entire levator muscle may be removed and the triangular ligament may be divided but the uterus will still retain its position provided the cardinal ligaments are intact. It is true however, that when the lower supporting structures have lost their integrity, long continued intra abdominal pressure exerted upon the fundus uteri will eventually stretch the cardinal ligaments until prolapse results.

The second group of holding structures is the pubocervical ligaments which are massed fibers of connective tissue extending from the lower posterior surface of the symphysis and pubic ramus to the cervix and blending with its wall up to the

level of the internal os. Laterally these fibers merge with the anterior aspect of the cardinal ligaments and are attached also to the true fascia of the bladder and vagina near the median line. These ligaments are strong supports of the uterus but are secondary in importance to the cardinal ligaments.

The third division comprises the so called sacro uterine ligaments which run from the posterior aspect of the cervix at its junction with the fundus backward and outward to the sacro iliac joints. Their effect in maintaining uterine position has been much overemphasized.

All of the above structures as has been said are designed to hold the uterus firmly in position, their elasticity permitting lateral or anteroposterior movement or even some transitory descent.

2 The supporting tissues of the uterus and adnexa are those of the pelvic diaphragm, the levator ani and coccygeus muscles with their enveloping fasciae and the triangular ligament, which fills in the triangle under the pubic arch and closes the space left by the failure of the two levators to unite anteriorly. This pelvic diaphragm forms a secondary support for the uterus, the muscles by their contraction resist the excessive downward pressure from above and by the maintenance of muscle tone they take at least a portion of the strain of holding the uterus from the cardinal ligament as well as from the associated tissues.

Fig 2 The section passes through the lower part of the coccyx and the spine of the ischium, through the middle of the acetabulum cutting the head of the femur 1, M coccygeus, 2, cervix at level of internal os, 3, connective tissue of the parametrium and cardinal ligaments, 4, fascia of obturator internus (Redrawn after Eycleshymer and Schoemaker *A Cross Section Anatomy*)

CAUSE OF PROLAPSE

The cause of prolapse lies in a relaxation of the cardinal ligaments, primarily, the descensus being facilitated by incompetence of the pelvic diaphragm resulting from injury or overstretching. That the holding apparatus is primarily responsible is shown by the fact that many women suffer for years from severe laceration of the pelvic floor with large rectoceles but there is no uterine descent whatever.

Conversely, it is noteworthy how many cases of complete prolapse reveal insignificant injury to the levators and the pelvic diaphragm. The term "hernia" has been applied often to uterine prolapse but the mechanism of this lesion does not seem to justify its use, the process being that of a true ptosis rather than a hernia. The writer has been long in accord with the view that simple mechanical factors are not sufficient to explain the occurrence of procidentia uteri, but that there must be some systemic condition present among women presenting this condition in addition to tissue injuries.

Dr Robert J Griffin, some years ago, made the interesting observation in Kensington Hospital that advanced dental caries was far more prevalent among women suffering from prolapse than in those patients of comparable age who entered the hospital with other pelvic disorders. Whether this phenomenon is merely a coincidence or a true relationship has yet to be shown, and the staff of this institution is now planning an investigation into the question of the metabolism of prolapse

cases in an attempt to throw some light upon the subject.

Defective carbohydrate mechanism as a factor in loss of muscular tone is well known and probably also plays a part in the etiology of prolapsus uteri. This fact has been emphasized by Campbell who presents a suggestive series of blood sugar studies made upon women with birth trauma.

MANAGEMENT OF UTERINE PROLAPSE

The non-operative treatment of prolapse, the use of the pessary in women who are bad surgical risks, the question of the type of operation to be preferred in women of child bearing age, pre-operative treatment, and so on are matters of paramount importance, but since this communication is limited to a consideration of certain surgical measures only, the other phases of the subject will not be considered.

Earlier surgical measures for the relief of prolapsus uteri generally included some intra-abdominal procedure as ventrofixation, the fascial interposition of Kocher, or uterine suspension in some form. Gradually the intraperitoneal portion of the operation has been abandoned until now most gynecologists utilize the vaginal approach alone and do not augment the operation by any form of abdominal elevation of the uterus.

The operations for the cure of prolapse in widespread use are, vaginal hysterectomy, the Watkins interposition, the Manchester or Fothergill operation, and the Le Fort procedure.

Fig. 3. The section passes through the upper part of the symphysis pubis and the tuberosity of the ischium hence below the external os. 1 M. quadratus femoris in obturator internus 3 connective tissue forming support of vault of vagina 4 rectum 5 vagina 6 m. pectineus 7 m. obturator externus (Redrawn after Eycleshymer and Schoemaker 1 *Cross Section Anatomy*)

The choice of operation which will best meet the indications in each particular case is a matter of the utmost importance and it would seem unwise to select one of the foregoing procedures and apply it to a large series of patients without reference to the type of prolapse peculiar to the individual patient. Each patient should be considered individually.

In the clinic of the writer vaginal hysterectomy in general is limited to patients presenting associated uterine lesions as multiple small fibroids chronic metritis severe cervicitis and the like. In the treatment of prolapse *per se* this operation plays a comparatively small part. When indicated however vaginal hysterectomy is of great value nor is it the purpose of the discussion to minimize the importance of extirpation of the uterus by this means.

It has long been the opinion of the writer that the supravaginal portion of the cervix forms the best foundation or bearing from which to secure support for the ptosed uterus and that such support is more easily obtained when the cardinal ligaments are allowed to remain intact rather than severed from their cervical insertion.

This principle may well be utilized even when hysterectomy is indicated, by performing this operation via the vaginal route but permitting the cervix to remain. In other words it is a vaginal supracervical hysterectomy. The remaining cervical stump is used as a support for the vault of the vagina.

An operation of this type was performed by the late J. M. Baldy many years ago but was never reported by him. Recently supracervical hysterectomy in prolapse has been excellently described by Richardson who has devised a technique by which the upper segment of the cervix is utilized as a support for the vaginal vault. The reader is referred to Richardson's paper for the details of this important addition to the surgical management of a prolapsed uterus.

Of the three remaining plans of treatment each controls 1 or more phases of procidentia admirably but fails to correct certain other aspects of the lesion. It is the purpose of this paper to point out the great advantages to be gained by utilizing 2 or even more of the specifically described operations under appropriate circumstances.

THE USE OF MULTIPLE OR COMPOSITE OPERATIONS

It Atkins interposition plus Manchester procedure. In a case of prolapse of the first type wherein the uterus is in complete procidentia but where neither the anterior nor the posterior vaginal wall has suffered much damage the descent is produced almost entirely by the relaxation and stretching of the connective tissue supports of the uterus the cardinal and the supplementary pubovesical and uterine small ligament. As has been stated cystocele is a negligible factor in cases of this type. Here the Manchester Fothergill technique gives admirable results because it

shortens and plicates the paracervical connective tissue and elevates the uterus to its proper plane in the pelvis. Under such circumstances then, an operation of one type is sufficient to meet the indications.

In the second type of prolapse, when there has been widespread injury to the anterior vaginal fasciæ and the levator ani, and when cystocele is a prominent factor, the Manchester operation is not so well suited. Even though the uterus be elevated properly, the thinned-out vesical fascia does not offer support firm enough to retain the herniated bladder, and recurrences of the cystocele in some measure is not uncommon if the Manchester procedure be used alone.

On the other hand the Watkins interposition operation is admirably fitted to buttress the weak fasciæ, the corpus uteri forming a plug which serves to close the hernial opening.

However, control of the cystocele is not sufficient. The holding structures of the uterus, the cardinal ligaments, are not affected by this procedure and hence the too frequent failure of the operation. The prolapse recurs even though the anteflexed uterine body continues to restrain the bladder. Under these circumstances the performance of a multiple or composite operation often solves a difficult problem. If a Watkins interposition maneuver is supplemented by a Manchester operation, all of the relaxed tissues will have been restored and all of the indications met.

In the third type of prolapse described, those cases in which either cystocele or rectocele complicates the procidentia, similar composite operations may be performed to advantage.

Vaginal hysterectomy plus Le Fort operation or partial colpocleisis. In certain instances when vaginal hysterectomy is indicated for prolapse by reason of some uterine pathology, it is found that the vaginal walls are extremely relaxed and all too often inversion of the vaginal vault a few months after operation renders the patient as unhappy as before. This accident occurs even after the most meticulous technique has been employed and even in the hands of the most accomplished gynecologists.

To avoid this unpleasant sequence, it is often advisable to combine vaginal hysterectomy with a partial colpocleisis or Le Fort operation. Such a plan is especially valuable in old women with marked loss of muscle tone and greatly stretched out vaginal canals. The apposition of the vaginal walls adds but little to the time of the operation and should not contribute to morbidity or mortality.

Watkins interposition plus Le Fort operation. Another troublesome form of prolapse is that in which a huge cystocele is attended by greatly relaxed vaginal walls, but the descensus of the uterus is not excessive. This lesion is fairly common among old women and is difficult to correct by any single operation. Here a Watkins interposition will maintain the bladder in position but the relaxed vaginal vault is best held by a Le Fort operation.

Indications for the employment of composite operations will occur to everyone engaged in gynecological surgery and, indeed, multiple operations are doubtless commonly utilized by operators in this field. It must be clearly understood, however, that many cases of prolapse are perfectly manageable by the performance of one of the standard procedures with adequate repair of the pelvic floor and with these cases the present discussion has no concern. However, in any series of operations for the relief of prolapse there are to be found a considerable number of failures, many of which would have been prevented had a composite operation been performed.

It has been thought unnecessary to include illustrations of the various operations under discussion since the technique of these procedures is common knowledge among gynecologists.

CONCLUSIONS

- 1 Prolapse of the uterus is due primarily to a relaxation and stretching of the parametrial connective tissue, the holding apparatus of the uterus.

- 2 Loss of tone and injury to the pelvic floor is a secondary factor in the etiology of prolapse. It is operative only because of the unbalance of the forces involved, namely the continuous downward thrust of intra-abdominal pressure which normally should be opposed by an elastic and strong pelvic diaphragm.

- 3 Prolapse cannot occur when the cardinal ligaments and other portions of the holding apparatus are tense and uninjured, regardless of the state of the pelvic floor. It can occur, however, when these ligaments have lost their tone even though the levator ani and associated muscles and fasciæ are comparatively uninjured.

- 4 From the viewpoint of surgical cure, prolapse must be divided into several clinical varieties, dependent upon the associated lesions.

- 5 The upper segment of the cervix uteri and its attached cardinal ligaments offer the best support to the uterus and vaginal vault, and hence vaginal hysterectomy should play but a small part in the surgery of prolapse *per se*. On the other hand, vaginal hysterectomy with the reten-

tion of a collar or disk of cervix (Richardson) is a well designed procedure of great value

6 The utilization of various operative techniques in the performance of multiple or composite operations when required to control prolapse of different types is the method of choice in the approach to this problem

WERTHEIM OPERATION FOR CANCER OF THE UTERUS

PROFESSOR PAUL WERNER *Vienna, Austria*

THE Wertheim operation for carcinoma of the uterus is not a new subject. Over 40 years ago my teacher, Wertheim, originated and developed the technique for this operation and this procedure has been improved further by countless gynecologists the world over. Nevertheless, the fight against cancer of the cervix, which claims thousands of women yearly, continues to stimulate most of us to still greater efforts.

It is my purpose to limit my remarks to a discussion of measures designed to reduce the high mortality rate resulting from the high incidence of postoperative peritonitis. Without doubt the Wertheim technique permits greater exposure, and therefore, a more extensive resection and a more satisfactory examination and removal of involved lymph glands than does any other surgical operation for cancer of the cervix. The Wertheim, therefore, fulfills the primary requirements for successful surgical procedures against cancer anywhere in the body. Despite this, we are obliged to admit that this operation has been discarded in the past few years by many surgeons in favor of other operative or non operative measures due to fear of the attending high mortality, which varies from 10 to 20 per cent with different surgeons, even 30 per cent according to reports in the literature of those patients in whom the Streptococcus hemolyticus could be recovered from the ulcer. The postoperative deaths are due largely to peritonitis. This is easy to understand, for the carcinoma is associated invariably with various pathogenic organisms so that the operation of necessity is performed in a septic field.

From the Department of Gynecology of the Rudolfsplatz in Vienna.

Presented in the Symposium on Obstetrics and Gynecology before the Clinical Congress of the American College of Surgeons New York October 17-21 1938

The latest suggestion to reduce the incidence of postoperative infection and peritonitis was made by Louros, of Athens, and presented by him in Amsterdam on May 4 1938 at the last International Congress for Obstetrics and Gynecology. He modifies an old idea of Zweifel who in order to reduce the possibility of infection resulting from the opening of the vagina from above, recommended burying the uterus deep in the pelvis after its separation from the bladder, rectum and walls of the pelvis, and re-peritonealizing over it with bladder and rectum. The abdomen is then closed, and the patient placed in the lithotomy position. After circumcising the vagina, the uterus is withdrawn and the parametrial wounds are packed. Louros adopted this method with a modification. He employs the mesosigmoid rectum, and mesorectum after closure of the parametrial slit instead of the bladder and rectal peritoneum. After the uterus is removed *per vaginam* he approximates and fixes the surfaces of the phica vesico uterine and recto uterine to the vaginal walls which are then closed. Louros maintains that his modification has these advantages: closure of the peritoneum is facilitated especially if inflammatory areas are present; injury to the bladder and rectum during the preparation of the peritoneal flaps is avoided; and finally, there is no communication between the parametrial wounds and the vagina.

Our method to avoid postoperative peritonitis is altogether different and is based upon the 3 following points:

The anesthetic. The entire field of operation must be considered potentially infected. With inadequate anesthesia the small bowel is forced down into the field of operation and may thereby be contaminated. For that matter even the repeated forced reposition of such a bowel will

injure the serosa rendering it less resistant to infection. Moreover, the separation of the rectum from the posterior vaginal wall is especially painful, a manipulation that will prompt the patient to move and to press down even under deep inhalation anesthesia. All this can be avoided only with a truly effective spinal anesthesia. Therefore, when doing a Wertheim operation, we employ spinal anesthesia exclusively, using 8 to 10 cubic centimeters of 0.1 per cent percaïne solution, and administer veronal and morphine as pre-operative sedation. Furthermore, this anesthesia effects complete relaxation facilitating gentle and quick manipulation.

Preparation Not only the superficial but also the deeper structures of the carcinomatous growth contain bacteria. Each manipulation of the tumor tends not only to force these bacteria still deeper into the uterine tissue but also to infect the entire surrounding connective tissue. For this reason no woman with cervical carcinoma should have a pelvic examination done for at least 2 days prior to the operation. Curettage, cauterization, or tamponade must also be avoided previous to operation. Wertheim, himself, used to curette and cauterize just before operating, believing that he could thereby remove infected and necrotic tissue. Such preparation is not only superfluous but, on occasion, is even dangerous.

Precautions To prevent the introduction of infected tissue fragments into the peritoneal cavity from the opened vagina Wertheim used right-angled clamps, the so called "knee-clamps," with which he clamped the vagina below the isolated tumor, dividing the vagina below the clamps. The application of these knee-clamps can be difficult occasionally, especially when the tumor extends far down into the vagina, furthermore, due to inaccessibility it is sometimes difficult to effect division of the vagina below the clamps. Therefore, we discontinued using them and divide the vagina in the following manner. Only after the rectum and bladder have been completely separated and the parametrium resected, so that the carcinomatous growth is supported solely by the vagina, is the vagina painstakingly cleaned with dry gauze from below. Two gauze sponges are introduced into the vagina as high as possible and against the carcinoma, following which, the vagina below this is again cleaned with dry gauze. The surgeon after changing gloves returns to the open abdomen. Grasping the specimen with the left index finger and thumb, and compressing the vagina below the gauze tampons, he opens the anterior vaginal wall with scissors at a level below his fingers. Through this opening then is intro-

duced another gauze tampon into the distal part of the vagina. Following this, division of the vagina is completed. When this technique is practiced it is always possible to prevent the introduction of cancerous fragments into the abdominal cavity.

The results achieved in our carcinomatous patients by the observation of these simple measures can be shown by a brief report of operative results. This routine was employed for the past 9 years, during which time 294 women with carcinoma of the cervix were admitted to our dispensary. Of these, 63 were considered inoperable at once from either physical examination alone or after exploratory laparotomy, and they were referred for irradiation therapy. So, 78.58 per cent of our patients fall into the operable class. In 1932, Halban stated that various surgeons report an average operability of 50 to 60 per cent. It, therefore, appears that our operability rate is rather high due to the fact that we also operate upon very advanced cases.

Two hundred and thirty-one women were operated upon, of these, 152 were operated upon according to the Wertheim technique, 65 according to Schauta-Schuchardt, 2 according to Halban, and 12 had a simple vaginal hysterectomy. The latter 12 were young women, with very early cancer, the diagnosis of which in most of them was established first through biopsy. The 67 patients who were operated upon according to Schauta-Schuchardt, or Halban, were also early cases, in whom the carcinoma was either restricted to the cervix or in whom the growth had extended but very little.

So these patients upon whom a Wertheim operation was performed included not only the advanced cases but also borderline cases. According to Winter's classification most of our patients would be included in Class III and even Class IV. This is proved by some notes taken from the operative findings. In 52 patients enlarged lymph-glands were found and extirpated, during which the obturator nerve in 1, the iliac vein in 6, and the iliac artery in 2 had to be resected because the carcinomatous glands so completely involved these structures that they could not otherwise be removed. In 40 patients it was exceedingly difficult to separate the bladder, it was actually necessary a few times to resect a small portion of it and once even the entire fundus of the bladder. In 33 patients considerable difficulty was encountered in separating the ureters (including 3 resections of the ureter), and in 6 difficulty in separating the rectum. In 11, extensive pelvic inflammatory changes were found, and in 6 patients the tumor

ruptured during the operation despite every precaution taken to prevent this. In 40 patients the parametrium was infiltrated laterally to such an extent that its complete removal exposed even the levator ani.

There were 12 deaths in these advanced cases a mortality rate of 7.96 per cent. There were 5 deaths due to pulmonary embolism, 2 to pneumonia, 1 postoperative hemorrhage, 1 to the anesthetic, 1 to cerebral edema, 1 to multiple sclerosis, and 1 to retroperitoneal abscess. The deaths due to pulmonary embolism occurred 1, 4, 5, 6, and 14 days, respectively, after operation despite the use of every precaution to prevent it. All were advanced cases in which large, raw surfaces remained due to the very extensive resection. The anesthetic death occurred in a woman whose inadequate spinal anesthesia had to be supported with 100 cubic centimeters of open ether. Here, the autopsy revealed a marked myocarditis. Death, in the patient with retroperitoneal abscess occurred 3½ months after operation; it is more

than likely that death in this case was due to poor postoperative care rather than to any fault of operative technique. When one considers that all these deaths occurred only in patients with advanced carcinoma of the cervix, the 8 per cent mortality rate is really rather low. At any rate we were able to perform 152 successive difficult Wertheim operations without 1 patient developing peritonitis. These results certainly appear to justify the points of technique mentioned.

I regret that it is impossible to compare our findings with those obtained by Louros with his technique and presented by him to the International Congress in Amsterdam because the reports of the Congress failed to include his results. However we believe that our technique saves time and is simpler, because it is unnecessary to change the position of the patient during the operation, thus permitting it to proceed without any interruption. The results obtained by this technique justify its further trial by our colleagues.

CERTAIN ASPECTS OF SO CALLED STERILITY IN THE FEMALE

A. D. CAMPBELL, M.D., C.M., F.A.C.S., M.C.O.G., F.R.C.S. (c), Montreal, Quebec

THE problem of sterility is one which concerns not only ourselves as gynecologists, but the general practitioner, the urologist, and the internist. The biochemist and the physiologist, while not directly concerned with the human problem, are able nevertheless to give invaluable aid to the clinician in the study of individual cases. Since distant foci of infection may influence the reproductive tract, even such an apparently remote specialty as otolaryngology may be able to render distinct help.

I should like in this brief communication to deal only with those cases in which the female is entirely at fault, and in whom, on examination, no lesion is apparent or palpable in the pelvic organs. Aldridge reported that 66 per cent of cases of sterility have partial or complete obstruction of the fallopian tubes and that in 44 per cent of these the pelvic examination is negative. It is probably common experience that about one-third of all cases of so called female sterility display no detectable lesion in the pelvis.

There are in this group of cases 3 main causes for the sterility which they manifest. In the first place, there may be no ovulation, in the second place, the liberated ova may be unable to find their way into and through the fallopian tubes, and in the third place, the condition of the reproductive tract in general, and of the endometrium in particular, may be inimical to fertilization, or perhaps more often to the maintenance and implantation of the fertilized ovum and the embryo. Of these 3 main divisions, the second appears to be, superficially at least, an anatomical or mechanical problem, whereas the first and third in the many instances are primarily problems in applied endocrinology, since the anterior pituitary hormones exercise chief control over the process of ovulation, and the hormones of the ovary itself regulate the development and activity of the tissues of the reproductive tract.

Occlusion of the fallopian tubes is often due to some mild inflammatory process. It should be borne in mind that peritoneal reaction as a result, for example, of regurgitation of blood through the

tubes in certain cases of abortion, or of irritation of a chemical nature caused by high pressure douches, or even ordinary soap-sud douches, such as are used so extensively in England, may lead to the production of occluding lesions which are not palpable. Tuberculosis must always be borne in mind, not only as a possible cause of sterility, but because of the appalling risks with which it invests procedures otherwise comparatively safe. I am anxious to insist upon this point, since I have seen 3 cases in which, though the history and the physical examination gave no warning, insufflation of the tubes precipitated active pelvic tuberculosis. Recently the lesson was emphasized by a fourth case in which tuberculosis of the endometrium was encountered on examining microscopic specimens of endometrium. Such a finding being pathognomonic of tuberculous salpingitis, a panhysterosalpingectomy was decided upon. When the abdomen was opened the tubes appeared to be perfectly normal, yet on microscopic examination the tubal mucosa was found to be studded with tubercles. In the light of these experiences the use of insufflation, which many employ lightly either for diagnostic or for therapeutic purposes, should be most carefully considered. The injection of iodized oil, furthermore, is not entirely free from danger (43).

It is to be considered, too, that even when sterility is actually due to tubal occlusion, or in more general terms to failure of the ova to attain the uterus, it is not necessarily futile to attack the problem by endocrinological methods.

Kaufman and others have shown that the administration of estrin not only causes the tubal musculature to develop, but actually leads to an enlargement of the lumen and development of the cilia. Seckinger and Snyder, as early as 1926, found that the activity of the muscular wall of the tube paralleled, chronologically, the changes in the endometrium and tubal mucosa, at mid-interval and for some days thereafter, the contractions were rapid and of varying amplitude, while in the premenstrual and menstrual phases, and throughout pregnancy, they were slower, smaller and more uniform.

In a recent experimental study Geist et al., using the method of Rubin as a means of recording the

tubal contractions, have shown quite conclusively that after the menopause, with the gradual cessation of production of estrogenic hormone, there is a marked impairment of activity of musculature of the fallopian tubes and gradual disappearance of the regular rhythmic tubal peristalsis. Coincident with the impairment in tubal contractility the vaginal smears exhibited signs of various degrees of estrin deficiency. The most marked deficiency was seen in those patients showing least tubal activity. Administration of estrin resulted in the development of rhythmic contraction waves of high amplitude similar to those observed in normal females. Simultaneously with the re appearance of tubal contraction the vaginal smears showed the full effects of estrin upon the mucosa. This excellent experimental study seems to justify our impression (4, 5) that impairment of tubal contractility, due to estrin deficiency, may play a rôle in some form of sterility and tubal pregnancy.

The transporting mechanism in the genital tract deserves further consideration. G. H. Parker has shown that the ciliated epithelial cells in the tubal mucosa waft the ova downward while the contractions in the tubes themselves appear to force the sperm upward. It is not inconceivable that an individual exaggeration of the upward directed force may, first, cause relative sterility by opposing the descent of the ova, second, by permitting premature fertilization or similarly by interference with the descent of the fertilized egg, tend to encourage ectopic gestations whose tendency to recur requires no emphasis, and third, by favoring upward migration of detached fragments of viable endometrium, play an important rôle in the causation of endometriosis. From time to time one encounters associations among these 3 phenomena which may have in common some endocrinological etiological factor.

It is also clear that deviation from normal in the endometrium may seriously affect the fertilized ovum before as well as after implantation. Since insemination will only rarely, take place at the very hour when the ovum awaits fertilization, it is most important that the female tract should be hospitable to the sperms. The presence of infection not only in the vagina but in the cervical canal is inimical to the life of the sperm. Such infection may not give rise to purulent discharge, but pathogenic and pyogenic organisms in the vagina have been said to be responsible for some 50 per cent of cases of sterility. Endometritis following the use of the stem pessary is an infection contributing to unsuccessful insemination.

Marshall and Jolly first demonstrated the effect of ovarian secretion on the vaginal mucosa.

The observations of Seguy and Vinneux suggest that the variations which occur in the hydrogen ion concentration and also in the physical character of the cervical secretions throughout the cycle may be of considerable importance in relation to the ascent of the sperm. They observed that at about mid cycle there was an increase in the hydrogen ion concentration and that coincident with this change, the secretion in the cervical canal became less tenacious and more translucent. It is possible that this comparatively simple procedure of testing the character and hydrogen ion concentration of the cervical secretion at different periods of the cycle may be found ultimately to be of value.

One may commence the endocrine investigation of cases of sterility by obtaining a detailed menstrual history. The apparent menstruation of early adolescence is of relatively little importance here since we believe that in many instances these demonstrations are only pseudomenstrual. In the immature rodent, an induced first cycle is usually anovulatory.

It is generally held that the corpus luteum is essential for normal menstrual cycles but I believe that this dogma must be modified as pointed out in a previous communication by Campbell and Collip (6). Moreover, Corner and Hartman have shown that the corpora lutea are not necessarily present in ovaries showing cyclic activity as manifested by menstruation.

Unfortunately pseudomenstruation is clinically indistinguishable from true menstruation. After the patient has reached her menstrual stride, an accurate history should be analyzed as to the length of the interval, the amplitude and duration of flow and the presence or absence of pain.

Sir Henry Whitehouse has stressed the difference between premenstrual pain (dysmenorrhea) and pain (menorhagia) occurring during the actual flow. The latter, in his experience, suggests a foreign body such as polyp, unshed endometrium or leiomyoma in the uterus while he finds premenstrual pain to be associated with a particularly highly developed progestational type of endometrium, the cells in the strata compacta simulating decidual cells, probably produced by too vigorous or too prolonged production of the hormone of the corpus luteum. Excessive duration of flow (over 5 days), or an increasing amount of hemorrhage, must always first suggest the presence of some occult lesion in the uterus or pelvic organs.

The length of the interval is probably the most significant single factor to be gleaned from the personal history. It is unfortunate that many women are convinced that their periods recur regularly.

every 28 days, when in fact accurate recording reveals considerable instability. In my experience it is exceptional for a woman whose cycles are shorter than 27 days to become pregnant, it may be that fertilization occurs, but the embryo is aborted on the twenty-seventh day, not having become firmly established before luteal function regressed. The length of the cycle depends upon the complex interactions between the ovary and the anterior pituitary, for, while the anterior lobe hormones determine follicular maturation and the formation of corpora lutea, the hypophysis is itself influenced by the hormones produced by the developing follicle and also by the hormone of the corpus luteum (11). If any link in this chain of stimulation and inhibition is weak, it may well happen that the corpus luteum can not of its own pituitary-controlled vitality sustain the endometrium until the twenty-eighth day of the cycle, until the time, that is, when the corpus luteum may be re-activated and vitalized by *prolan* produced by the developing and implanted embryo. In such cases, the outlook becomes more hopeful if it is found possible to increase the length of the interval, even if only an occasional cycle reaches the desired length, there is always hope that a pregnancy may be successfully established on 1 of these favorable occasions.

More detailed endocrine investigation is a matter of greater practical difficulty, biological assays of estrin and other sex hormones in the urine, or more rarely in the blood, has been practiced with success by Frank et al., Fluhmann (22, 23, 24), and many others, but it demands the services of a competent biochemist, and is vastly expensive both in regard to time and animal material if efficiently done.

To make a really complete survey of the endocrine status of each case, it would be necessary to assay each and every one of the plurality of pituitary hormones, at present an inconceivable task. Furthermore, it emerges from the work of Collip (12, 13, 14, 15) and his associates that to each of these hormones there may be an antagonistic anti-hormone which would also have to be measured quantitatively, there is indeed evidence of the presence of such substances in the blood of many patients with amenorrhea. Moreover, since both the ovarian and the pituitary hormones are produced in fluctuating quantity, biological analysis of single or occasional samples of blood or urine can never fully enlighten us as to the endocrine levels throughout the cycle.

Study of the structure of the endometrium is also open to this objection, that it furnishes only an instantaneous cross-section of a continuously

changing function; nevertheless, valuable information may be obtained in this way. Bland found that in some 23 per cent of sterility cases the premenstrual endometrium strongly suggested anovulatory cycles, Mazer encountered this still more frequently. One may avoid the risk of damaging a healthy endometrium, or even of interfering with an early pregnancy, by obtaining samples within 10 hours of the onset of bleeding. Properly interpreted, the slides reveal fairly accurately the course of events in ovarian activity in the preceding period, though of course only very roughly quantitative evaluations can be made on the basis of microscopic examination.

The time of ovulation can be assumed in a few instances, where it is marked by pain or by slight hemorrhage, but in the majority of cases the determination presents a formidable problem. Sudden increases in excretion of prolactin, and perhaps of estrin, may serve as markers, but the cost and difficulty, as previously mentioned, of detecting them restrict their use. The electrical detection of ovulation of Burr and Allen, requires much elaboration before it can be of practical clinical use. Special attention should be drawn to the most helpful and extremely important work of Venning and Browne (44, 45). They have established a relatively simple chemical procedure for measuring the quantity of pregnandiol excreted in the urine, since pregnandiol is apparently the inactive excretion form of progesterone, the hormone of the corpus luteum, this makes it possible to determine, without too much difficulty, the time when the corpus luteum begins to function as an endocrine organ, i.e., just after ovulation, and to form some estimate of its activity and vigor throughout its active life. Thus in a patient in whom pregnandiol constantly appears at some time other than the fourteenth day of the cycle, one may recommend coitus at or about the time thus indicated. Again, a decreased pregnandiol output in early pregnancy may be regarded as a warning of a threatening abortion, which can possibly be averted by administration of appropriate amounts of progesterone (45). As shown in the recent work of Deanesly and Parkes, there is perhaps the possibility that the implantation of specially prepared discs of crystalline progesterone may afford a practical method of the clinical use of the hormone. However, the appearance of pregnandiol is no certain indication that ovulation as opposed to corpus luteum formation has actually taken place, and of course is no suggestion at all that the ovum is able to pass into the muellerian tract.

Among other aids to endocrinological investigation which have been found helpful, special refer-

ence should be made to the work of Mortimer (34, 35, 36) in using the cranial skiagram as an indicator of anterior pituitary function past and present. While the shape and size of the sella turcica have been widely used as occasional signs of pituitary abnormality, the outline of any ductless gland is of little guide to physiological activity. Mortimer has called attention more especially to the structure of the calvaria and the degree of development of the paranasal sinuses. Since these are largely controlled by the pituitary growth hormone, and since they change in their form and interrelations during the period of growth, they throw light on the previous activity of the pituitary. For example the prognosis is not bright in cases of menstrual disorder or apparent sterility, if there is early cranial sclerosis with poor development of the accessory sinuses.

It is always desirable to remember that the endocrine system functions, as an integrated whole, and that disturbances apparently remote from the reproductive tract may have a considerable bearing on the question of sterility. The net should therefore be flung widely in search of possible causes of this condition. The thyroid gland, for example, has a profound influence on reproduction, and a basal metabolic rate should be obtained in all cases, although one sometimes doubts whether an apparently normal basal rate can be taken as reliable assurance that the thyroid function is perfectly normal.

Abnormalities of carbohydrate metabolism may also serve as indicators of endocrine disorder, it is noteworthy that menstrual cycles are suspended or disturbed in some 90 per cent of diabetic women of childbearing age and reappear when the diabetes is properly controlled (39). Still more important is the fact that sterility is not infrequently associated with disturbances of sugar tolerance which may not necessarily be frankly diabetic in type and that pregnancy may follow the administration of insulin and it should be emphasized that glycosuria may be completely absent and fasting blood sugar levels substantially normal in many individuals whose response to the ingestion of sugar in a tolerance test is altogether faulty and inadequate (38). Some 20 per cent of cases with definitely disturbed carbohydrate metabolism do not show glycosuria. It may be noted here that in these cases, as well as in hyperthyroidism protein catabolism may be increased and thus require an unusually high intake of protein of a high biological or protein sparing value (39).

Nutritional factors indeed, often require some consideration. The normal reproductive rhythm is one of the first bodily functions to become dis-

ordered when the supplies of good quality protein, or of any of the essential minerals or vitamins is inadequate, as the experience of Central European countries during 1916-1919 sufficiently shows. It has frequently been urged, for example that there is a correlation between sterility and secondary anemia. Dr. Rolland Kennedy, however, in a recent review (unpublished) of mothers attending the child welfare clinic in Montreal found that 43 per cent of a series of 1,500 women of child bearing age showed a relative anemia without any disturbance in their menstrual cycles or interference with pregnancy. Since loss of iron rich blood at menstruation is an important factor in this type of anemia, it is not altogether surprising that there is no correlation apparent between amenorrhea and anemia in a large series of cases.

The endocrine preparations available for therapeutic measures are numerous, but fall into 2 main types as far as their direct influence upon the reproductive tract is concerned. There are first, the ovary stimulating or at least ovary affecting substances obtained either from the pituitary gland itself, or from the serum of pregnant mares or from human placenta or pregnancy urine. There are second, the hormones of the ovary itself and their various natural and artificial derivatives.

In the first group we have made use both of the gonadotrophic or maturity fraction of anterior pituitary extract, and of the anterior pituitary like (19) (APL) fraction from pregnancy urine. Collip et al. (16) showed that while both these substances produce luteinization in the ovaries of intact mature rats or mice they are nevertheless, fundamentally different. The urinary products are comparatively inert in hypophysectomized animals and apparently require at least the passive co-operation of the animal's own pituitary gland to unfold their usual effects (17). Even so, they have relatively little power to produce genuine ovulation (18). We (7) have found that anterior pituitary like is capable of correcting certain menstrual disorders. It is of value in the treatment of cases with moderate intermittent intermenstrual hemorrhage, and tends to re-establish normal cycles when there is persistent uterine bleeding due to endometrial hyperplasia or metropathia hemorrhagica (9). Since many patients have become pregnant during or after such treatment, it appears that though anterior pituitary like may be incapable of producing ovulation on its own account it has no adverse effect. Anterior pituitary like should be reserved for cases with obvious disturbance of the endometrium, while the pituitary gonadotrophic extract is indicated when sterility persists in the presence of more or less

TABLE I—ANALYSIS OF CASES CONSERVATIVELY TREATED WITH EMMENIN

	Cases	
Number of patients treated	34	
Average age of patients, in years	33	
Age of 2 patients at first pregnancy	42	
Years of sterility	2 5	
Average menstrual periods after treatment	1 5	
Number of failures	7

normal menstrual cycles, since it is more likely to stimulate true ovulation

The ovarian hormones, now available in manifold forms, some of them of enhanced potency in practice, have also their part to play. In 1930, Collip (8) obtained from human placentas a water-soluble, ether-insoluble, orally-active factor to which the name "emmenin" was given, it is probable that at least the chief active principle in this fraction is similar or identical to the glycuronide of estriol later isolated from urine by Marian. Emmenin differs from estrone (theelin) in being highly active orally in immature intact rodents (8), but relatively inert in adult castrates. It is with this preparation that I have the most personal experience. The emmenin complex has been found to be of value in the correction of oligomenorrhea (7), even when the menstrual flow, having gradually diminished over a long time, has for some months altogether ceased. On the other hand, suddenly appearing breakage of a previously normal menstrual rhythm is less amenable. In our experience, cycles of normal length are not disturbed by emmenin administration, but in a certain number of cases, short cycles have been lengthened in this way by 1 to 3 days, which probably indicates that emmenin can have a regulating influence upon the pituitary. The normal-

izing of a somewhat short cycle, as already suggested, is often an invaluable step toward overcoming an apparently causeless sterility. Several patients, receiving emmenin treatment for menstrual disorders, oligomenorrhea or dysmenorrhea, became pregnant; still more successful has been the treatment of patients with sterility but with normal cycles. Since in my experience no patient on a cycle persistently shorter than 27 days became pregnant, only those attaining cycles of normal length are analyzed (Table I).

SOME POINTS OF INTEREST IN CONNECTION WITH CASES STUDIED

CASE 1 The patient who had been given emmenin became pregnant and continued the treatment for 3 months. She delivered at term by means of cesarean section. One year later the patient again became pregnant but without treatment with emmenin and she aborted after the third month. The following year she received medication for 3 months and at the present writing has been pregnant for 7 months.

CASE 6 This patient aborted in second month probably because of early discontinuance of medication. Later when treatment was continued past the third month she delivered at term. This same occurrence holds true of 2 other occasions.

CASE 12 This patient, a hypophyseal dwarf, began menstruation at the age of 17. It was acyclic, occurring only 2 or 3 times yearly. Emmenin was administered and she became pregnant. A premature male, dead, was delivered by cesarean section in another city.

CASE 14 The patient, suffering with oligomenorrhea, had periods of amenorrhea up to a year throughout menstrual life.

CASE 19 This patient, a chronic nephritic, as later events revealed, became pregnant on treatment but in the last month of gestation abruptio placentæ occurred. She was then sterile for 3 years but became pregnant when treated with emmenin. This terminated in ectopic gestation 6 weeks later.

CASE 20 The past history of this patient disclosed that the first pregnancy terminated as pre-eclamptic toxemia with stillbirth. Two years later she had an ectopic gestation and was then sterile for 2 years. Upon treatment with emmenin she became pregnant and delivered at term. There was no toxemia.

CASE 23 This patient, unipara, was 42 years of age. She vomited throughout pregnancy during which she developed edema, and in the last trimester high blood pressure.

CASE 26 The patient developed moderate edema during the last month of gestation without increased blood pressure. The weight of the child was slightly over 11 1/2 pounds.

Seven patients with no apparent lesion in the pelvis did not become pregnant, later events proved the following:

CASE 23 The patient had pyonephrosis and also pealike submucosal fibroids.

CASE 34 In this patient tuberculosis was present throughout the entire muellerian tract (referred to in text).

Of the 5 cases remaining regarded as failures, no explanation for their sterility can be put forward.

While this series (which extends over a period of 9 years) is small, it would seem that the weights of the offspring of patients becoming pregnant on emmenin are unusually large though from calculated dates there was no evidence of postmaturity. Probably the same pertains when pregnancy follows other similar forms of hormone therapy.

Experience would lead one to suggest that sterility frequently results from deranged function of the muellerian tract as a whole or its transporting mechanism in particular, which in many instances can probably be corrected by emmenin therapy (27-40). It is well to observe here that when women who have previously appeared sterile become pregnant spontaneously, they show a considerable tendency to abort, and this is true also of women who become pregnant during treatment with emmenin. We have however encountered this difficulty only twice since we instituted the practice of continuing the emmenin treatment through the first 3 months of pregnancy.

Maturity fractions of the anterior pituitary gland are reserved for patients who after a 3 months trial of emmenin do not become pregnant and those who after biological investigations appear to be anovulatory.

It is particularly worthy of note that patients who become pregnant while taking emmenin or commence treatment on missing 1 menstrual epoch very rarely have vomiting of early pregnancy or display symptoms of so called toxemia in the last trimester.

MY EXPERIENCE WITH THE MELHADO MANEUVER FOR PERSISTENT POSTERIOR POSITION

GEORGE M WHITE, M D , M C O G , F A C S , St. John, New Brunswick

THE delivery in persistent posterior position remains one of the most difficult problems in obstetrics. It tests the judgment and skill of the obstetrician as much or more than any other problem in his practice.

The occurrence of this condition seems to vary somewhat in different parts of the world, or at least the statistics issued by different writers vary. In Eden and Holland's textbook, posterior positions are given as 25 per cent of all obstetrical cases. The figures of Douglas Miller, Edinburgh Maternity Hospital, are 18 per cent. Many years ago the late Professor Williams gave the figures from Johns Hopkins Hospital as 11.3 per cent, and Cragin in a large number of cases at the Sloane Hospital gave the figures as 17 per cent. So you see we have here 4 very reliable sources with the figures varying from 11 per cent to 25 per cent. One is inclined to believe that they are more liable to be underestimated than overestimated. As one is employed in this work he finds that he recognizes more and more posterior positions that rotate spontaneously and do not become persistent. It is probably fairly accurate to say 75 to 85 per cent of all posterior positions rotate spontaneously, so that only from 15 to 25 per cent remain as persistent posterior positions or deep transverse arrests.

You will notice from the heading of my paper that I have no intention of discussing posterior positions as a whole. I am fully aware of the fact that this condition is handled by many men in many ways with excellent results. It was my privilege during my years of training at the Royal Victoria Hospital, in Montreal, to learn this method of handling posterior positions. I believe that it is a good maneuver. I hope to show that the results obtained by others using this method, and more recently my own, compare favorably with the results of any other method used. I do not believe this method should be used to the exclusion of every other method, but I do believe in my own hands it is better for me than any other maneuver. I think every man should use the

before the Clinical Congress of the American College of Surgeons,
New York, October 17-21, 1938.

method in which he is most skilled and from which he obtains the best results. So I shall not discuss the etiology of posterior positions nor other methods of delivery, but I shall touch on the methods of diagnosis and the importance diagnosis has on the conduct of labor.

In my own private cases I very often can make a diagnosis of a posterior position during the office visits of the last month. Some of these pregnancies are definitely engaged in a posterior position, and some are not well engaged and arouse one's suspicion, as they will in all probability engage in a posterior position. This is a help in the cases at one's office, but often I am called in consultation by an interne with a public patient or by a fellow practitioner with a private patient of his own. I make it a rule, regardless of the time of day or night, that when a patient is admitted to the hospital in labor, to examine her as soon as possible and make a diagnosis as to the position. I believe that this is very important in planning the conduct of the labor.

If I find a breech in the fundus, the resistant plane of the back well out on the right flank with the small parts of the left side well up in front, and much more readily palpable than in an anterior position, the head not well engaged, the cephalic prominence on the left side, the fetal heart well out in the right flank, or sometimes on the left side just near the midline, then I strongly suspect a posterior position. If on rectal examination the head is high and not well engaged, or if the head is engaged and the sagittal suture felt in the right oblique, then my diagnosis is complete.

They are not all as easy as this. Frequently rectal examinations are not satisfactory. If after a reasonable number of hours of good labor I am in doubt of the diagnosis or have not a clear conception of the position, or of the mechanism of labor that is going on, then, under anesthetic with proper sterile technique, I do a vaginal examination. During this examination I try to decide in what diameter the sagittal suture is lying, where the anterior and posterior fontanelles are, the position of the ears, the condition of the cervix, how much it is effaced, and how much it is dilated, and from this examination I am able to decide whether I have a persistent posterior position.

The character of the labor often leads one to suspect a posterior position which may not have been diagnosed. Many posterior positions go by the expected date. The first stage is often long and drawn out with a poor quality of uterine contractions and excessive pain in the back. The cervix is slow to efface and dilate and the head remains high. A great many of these cases have the membranes rupture early, so that the first stage of a posterior position is a very unsatisfactory part of labor.

In the diagnosis of posterior positions I always warn my students not to be misled by the position of the point of maximum intensity of the fetal heart. In a right posterior this is most often well out in the right flank, but if deflexion has occurred and the fetal chest is thrown well forward and up against the mother's abdominal wall, it may then be heard best on the left side, very much in the position of a left occipito-anterior. However, this should not mislead us. One always has the x ray to help him, and in cases in which the diagnosis is difficult I have no hesitation in using it.

There is 1 point in regard to the cervix, that I have noticed, which has been a help to me. In anterior positions the cervix, after it is taken up and before dilatation begins, is often very far posterior and hard to reach, whereas in posterior positions this external os is often missed because of the fact that it is so far anterior. So often I have an interne tell me he thinks the cervix is fully dilated because he cannot find the opening, and on rectal examination I find the cervix way up in front almost under the symphysis and not dilated. I have at times missed the diagnosis of a posterior position during the whole of the first stage, until the cervix was fully dilated and the head driven down below the spines, sometimes as a posterior, sometimes as a deep transverse arrest. Then the patient may have strong bearing down pains with the head almost in sight, but showing no pressure on the perineum, no relaxation of the anal sphincter and without proper progress. This is characteristic of a persistent posterior position.

So I use in the diagnosis of posterior positions, first abdominal and rectal examination, then a vaginal examination if necessary, and finally the x ray.

Having made the diagnosis we must now plan the conduct of the labor. During the first stage the patient will require a considerable amount of care and attention. The studied use of sedatives both as to kind and amount is important. As we mentioned before the first stage of labor in these cases is liable to be long drawn out and unsatis-

factory. The patient requires appropriate sustaining treatment as well as sedation. I have found here that the combined use of intravenous glucose and subcutaneous morphine gives excellent results. I think it is important to remember that no interference is justifiable until the cervix is effaced and dilated and the presenting part in the pelvic brim. This is the period of watchful waiting of which we have heard so much.

After these conditions have been fulfilled and the contractions are continuing but progress has stopped or nearly so for $1\frac{1}{2}$ or 2 hours, it is time to desert our practice of *masterful inactivity* and to interfere, in the interests of the mother and child. If the cervix is not fully dilated but is dilatable and there are signs of fetal distress, it is sometimes necessary to interfere a little sooner than one would if the conditions were better. I think it is just here in the conduct of labor that one has to use his nicest judgment to decide when to interfere and I do not believe there is any one rule that will cover every case. But that as labor progresses and is closely watched, one must decide the most opportune time in the interests of both mother and child.

Dr DeLee says, 'the posterior position itself, and the operations performed because of it, cause untold and untellable maternal and infant suffering—the child's brains are damaged and the mother's soft parts lacerated and destroyed'.

The following tables give a review of Dr Melhado's cases as published by him in 1933.

TABLE I—GENERAL REVIEW OF MELHADO'S
976 CASES

	Cases	Per cent
Primiparas	513	52.5
Multiparas	463	47.5
Complete tears	71	7.3
Maternal morbidity	249	24.4
Fetal mortality	44	4.5

There were 976 cases of occipitoposterior position delivered during a period of 6 years at the Royal Victoria Ho. pital, 513 primiparas and 463 multiparas. There were 71 complete tears, maternal morbidity occurred in 249 cases or 24.4 per cent. The standard of morbidity used was a single rise of temperature to 100.6 degrees, occurring during the puerperium after the first 24 hours. Fetal deaths were 44 or 4.5 per cent. These included stillborn and those that died during the first 2 weeks of life.

The interesting thing to note from Table II is that both the fetal mortality and the maternal morbidity increased with the failure of anterior rotation.

TABLE II—ANALYSIS OF 392 SPONTANEOUS DELIVERIES*

Procedure	Number	Maternal number	Mortality per cent	Maternal number	Morbidity per cent	Fetal number	Mortality per cent
Anterior rotation	284	0	0	52	18.6	2	7
Face to pubis	108	0	0	33	30.5	6	5.5

*This represents 40.1 per cent of 976 cases

TABLE III—ANALYSIS OF 584 OPERATIVE CASES*

Procedure	Number	Maternal number	Mortality per cent	Maternal number	Morbidity per cent	Fetal number	Mortality per cent
Low forceps	157	2	1.24	37	23.5	4	2.48
Classical midforceps	209	1	.40	58	27.2	16	7.60
Scanzoni operation	67	0	0	17	25.3	5	7.46
High forceps	44	0	0	24	55.5	4	11.10
Melhado maneuver	107	0	0	27	26.1	2	1.80

*This represents 59.8 per cent of 976 cases

In his summary Melhado has called attention to the following facts. There is a close similarity in the morbidity rate among all forceps operations, the morbidity rate is increased with failure of anterior rotation whether the labor was spontaneous or operative, and the best fetal results, apart from spontaneous anterior rotation and spontaneous delivery, were obtained when the Melhado maneuver was employed.

PROCEDURE

It is our custom not to interfere during the first stage of labor, except by those therapeutic methods which aim at the relief of pain. After complete dilatation of the cervix, labor is allowed to progress naturally as long as the head is advancing rapidly. Failure of the head to advance demands immediate determination of the cause and its correction. It is usual in such cases that we find the membranes ruptured, the sagittal suture of the child's head lying in one or other oblique with occiput behind, or in the transverse diameter of the pelvis. Flexion of the head is, as a rule, imperfect, the head being engaged in the pelvis. There may or may not be undue molding, depending on the duration of the second stage. With the whole hand in the vagina, the perineum and pelvic floor are thoroughly dilated. The entire head is carefully palpated, if necessary, to make a correct diagnosis as to the position, the

degree of molding, and the type of head. The head is dislodged completely and pushed up above the pelvic brim. The hand is passed through the cervix beyond the occiput. If any resistance is encountered, such as a contraction ring around the neck, it is carefully "ironed out." The anterior shoulder is palpated and its position determined. If the shoulder appears to be directed forward, it is ignored; if the child's back is found to be directed toward the maternal back, the shoulder is carried forward as far toward the

anteroposterior diameter as possible. The head is now placed so that it lies with the sagittal suture in the transverse diameter of the brim, the posterior ear resting in the palm of the hand. The back of the hand will then be lying on the promontory of the sacrum. The posterior blade of the forceps is applied along the palm and placed exactly over the posterior ear, with the pelvic curve toward the occiput. The handle of the forceps is held by an assistant to prevent slipping

TABLE V—ANALYSIS OF 124 SPONTANEOUS DELIVERIES

Procedure	Number	Maternal number	Mortality per cent	Maternal number	Morbidity per cent	Fetal number	Mortality per cent
Anterior rotation	61	0	0	10	16.1	0	0
Face to pubis	12	0	0	4	33.3	0	0

TABLE VI—AUTHOR'S CASES DELIVERED BY MELHADO MANEUVER

Fetal mortality	0	0

during the application of the second blade. The hand is then withdrawn, and the anterior blade is carefully passed across the face of the child until it lies over the anterior ear, i.e., directly opposite the first blade. There can be no possible danger of injury to the bladder during this or any subsequent part of the procedure because all manipulations are done above the brim of the pelvis where there is plenty of room. The forceps are then locked. A gentle movement of 45 degrees rotation is imparted to the forceps, the object of this movement being to bring the occiput to an obliquely anterior position. Every step in the maneuver up to the present time is done with the head free from the pelvic control. The head is now lying within the forceps at the brim of the pelvis; the sagittal suture is in relationship with one of the oblique diameters, and the occiput is obliquely anterior.

With traction, the head is once more brought down into the pelvis. It is astonishing the ease with which the head descends on to the pelvic floor and delivery is accomplished. Usually in this method, the head is brought down in the opposite oblique diameter to that which it originally occupied, i.e., the right occipitoposterior position after rotation to become a right occipito-anterior position and the left occipitoposterior position a left occipito anterior position (the left hand used in right position and vice versa).

In the delivery of my own cases of posterior positions, the results of which I quote below, I have endeavored to follow this maneuver as closely as possible. Certain criticisms of this method have been offered, in that dislodging the head from the pelvis increases the danger of prolapse of the cord. In neither Dr Melhado's

original cases nor in any of my own did this happen. It has also been pointed out to me that in the application of the forceps above the brim of the pelvis, one is doing a high forceps but dislodging a head that has engaged and molded, and bringing it back into the pelvis in a corrected position, is entirely different from dragging a head that has never been engaged into the pelvis.

In conclusion I would like to present two more tables to show a comparison of the fetal mortality results from different methods of delivery of persistent posterior positions.

These are the figures of fetal mortality published by outstanding men in different parts of the world. In Table VIII I present the fetal mortality resulting from different methods of delivery of posterior positions in the Royal Victoria Hospital over a period of 6 years.

My series of cases have been few in number as compared with those of men working in larger places, and they have been scattered over a period of 5 years, and have included both private and public patients. Nevertheless I think the fact that I have not had one fetal death, speaks well for this particular method of delivery.

SURGERY ON HANDICAPPED PATIENT

SURGICAL PROBLEMS IN JAUNDICED PATIENTS

ROBERT S. DINSMORE, M D , F A C S , Cleveland, Ohio

JAUNDICE is a symptom and not a disease entity, and because of this one must decide at its onset whether he is dealing with blood dyscrasia, primary disease of the liver or biliary tract, or a mechanical obstruction

The history in this condition is always very important to the surgeon. In addition to ascertaining whether the jaundice has been transient or persistent, a knowledge of the absence or presence of pain and its character, particularly in relation to the jaundice, has been the surgeon's chief aid in making a decision in a large number of his operative cases. The history of previous operations on the biliary tract is disconcerting to the surgeon but, if these have been performed, he must know their exact nature and extent, that is, whether the operation was a cholecystostomy or a cholecystectomy. More specifically he must know how long drainage persisted after the first operation and also the time of appearance of the jaundice in relation to operation. It is a privilege to make the first incision in any biliary operation, particularly in the deeply jaundiced patient.

According to Hartman 25 per cent of all cases of jaundice are due to the gall stone or associated conditions (30 per cent in our own experience), and 30 per cent to carcinoma, either of primary or metastatic nature in the region of the pancreas and ducts. It is also significant that in only 25 per cent of the cases, including both toxic and infectious, is the jaundice due to lesions of the parenchyma of the liver. From these figures, it must be concluded that even a conservative estimate indicates that exploration should be performed in well over one-half of all patients with jaundice. Bitter experience has taught the surgeon that, due to the ever increasing number of drugs in use today, toxic hepatitis should also be considered as a possible cause of jaundice.

Hemolytic jaundice can not be discussed except to state that careful studies of the blood should rule out this possibility. Associated stones, however, may be a complicating factor causing either cholecystitis or obstruction of the common duct.

From the Cleveland Clinic

Presented in the Symposium on Surgical Procedures on the Handicapped Patient, before the Clinical Congress of the American College of Surgeons, New York, October 17-21, 1938.

It is unfortunate that cholecystography is contra-indicated in jaundiced patients. Occasionally, however, a flat plate of the right upper quadrant of the abdomen may be of great assistance in arriving at a diagnosis. The radiologists have stressed the point that these plates should be taken with at least 2 or 3 different penetrations and with the bowels completely evacuated.

In spite of all the refinements in diagnosis, the surgeon still sees certain cases in which an exploratory operation must be done to determine the true cause of the jaundice. In 2 instances during the past year, even after the most complete and exhaustive studies, I have operated and found that each of the patients had a very small atrophic liver which caused the jaundice.

PRE-OPERATIVE PREPARATION

In general surgery it is becoming increasingly obvious that in many cases of chronic illness requiring surgery, adequate pre-operative periods of preparation are essential. It is no longer good surgical judgment to send such patients into the hospital one day and operate the following day. The lowered mortality rates following the use of a careful pre-operative routine in many special fields bears testament to this fact, which was probably first emphasized by the men doing thyroid and genito-urinary work. Many lesions of the gastro-intestinal tract, such as dilatation of the stomach, chronic obstruction, and all conditions of the colon, as well as many cases of chronic disease of the chest, were formerly considered as emergencies, but now the patients are prepared for operation over a period of several days. This is particularly true of the jaundiced patient if a low mortality rate is to be maintained. Unquestionably, this factor has been more important than improvement in operative technique. Ordinarily it requires from 4 to 7 days and, as a general rule, it is better to extend the pre-operative period than to shorten it if the patient is improving.

The surgeon is primarily interested in the degree of liver damage which has taken place, for he recognizes that a chronic infection of the intra-hepatic ducts must be considered as an almost

SURGERY ON HANDICAPPED PATIENT

SURGICAL PROBLEMS IN JAUNDICED PATIENTS

ROBERT S. DINSMORE, M D , F A C S , Cleveland, Ohio

JAUNDICE is a symptom and not a disease entity, and because of this one must decide at its onset whether he is dealing with blood dyscrasia, primary disease of the liver or biliary tract, or a mechanical obstruction

The history in this condition is always very important to the surgeon. In addition to ascertaining whether the jaundice has been transient or persistent, a knowledge of the absence or presence of pain and its character, particularly in relation to the jaundice, has been the surgeon's chief aid in making a decision in a large number of his operative cases. The history of previous operations on the biliary tract is disconcerting to the surgeon but, if these have been performed, he must know their exact nature and extent, that is, whether the operation was a cholecystostomy or a cholecystectomy. More specifically he must know how long drainage persisted after the first operation and also the time of appearance of the jaundice in relation to operation. It is a privilege to make the first incision in any biliary operation, particularly in the deeply jaundiced patient.

According to Hartman 25 per cent of all cases of jaundice are due to the gall stone or associated conditions (30 per cent in our own experience), and 30 per cent to carcinoma, either of primary or metastatic nature in the region of the pancreas and ducts. It is also significant that in only 25 per cent of the cases, including both toxic and infectious, is the jaundice due to lesions of the parenchyma of the liver. From these figures, it must be concluded that even a conservative estimate indicates that exploration should be performed in well over one-half of all patients with jaundice. Bitter experience has taught the surgeon that, due to the ever increasing number of drugs in use today, toxic hepatitis should also be considered as a possible cause of jaundice.

Hemolytic jaundice can not be discussed except to state that careful studies of the blood should rule out this possibility. Associated stones, however, may be a complicating factor causing either cholecystitis or obstruction of the common duct.

It is unfortunate that cholecystography is contra-indicated in jaundiced patients. Occasionally, however, a flat plate of the right upper quadrant of the abdomen may be of great assistance in arriving at a diagnosis. The radiologists have stressed the point that these plates should be taken with at least 2 or 3 different penetrations and with the bowels completely evacuated.

In spite of all the refinements in diagnosis, the surgeon still sees certain cases in which an exploratory operation must be done to determine the true cause of the jaundice. In 2 instances during the past year, even after the most complete and exhaustive studies, I have operated and found that each of the patients had a very small atrophic liver which caused the jaundice.

PRE-OPERATIVE PREPARATION

In general surgery it is becoming increasingly obvious that in many cases of chronic illness requiring surgery, adequate pre-operative periods of preparation are essential. It is no longer good surgical judgment to send such patients into the hospital one day and operate the following day. The lowered mortality rates following the use of a careful pre-operative routine in many special fields bears testament to this fact, which was probably first emphasized by the men doing thyroid and genito-urinary work. Many lesions of the gastro-intestinal tract, such as dilatation of the stomach, chronic obstruction, and all conditions of the colon, as well as many cases of chronic disease of the chest, were formerly considered as emergencies, but now the patients are prepared for operation over a period of several days. This is particularly true of the jaundiced patient if a low mortality rate is to be maintained. Unquestionably, this factor has been more important than improvement in operative technique. Ordinarily it requires from 4 to 7 days and, as a general rule, it is better to extend the pre-operative period than to shorten it if the patient is improving.

The surgeon is primarily interested in the degree of liver damage which has taken place, for he recognizes that a chronic infection of the intra-hepatic ducts must be considered as an almost

From the Cleveland Clinic
Presented in the Symposium on Surgical Procedures on the Handicapped Patient, before the Clinical Congress of the American College of Surgeons, New York, October 17-21, 1938

constant factor in obstruction accompanying choledocholithiasis. The surgeon wishes to know specifically the following points about the patient upon whom he is to operate: (1) the function of the liver, (2) the level of the serum bilirubin, (3) the coagulation time of the blood, (4) renal function studies, (5) the roentgen findings in the flat plates of the right upper quadrant, and (6) if a postoperative fistula is present to have cholangiographic studies.

We know that patients who are suffering with jaundice have a tendency to bleed after operation but as Mason has stated, no test has yet been devised which can be relied upon to indicate that postoperative bleeding will not occur. Although there is some controversy as to whether the lack of available calcium is one of the factors in this hemorrhagic tendency, I still feel that the administration of calcium should be a part of the pre-operative routine. We are indebted to Lee and Vincent, Whipple, and Walters particularly for repeatedly emphasizing this precaution and recommending that 5 cubic centimeters of the 10 per cent solution be given each day during the entire pre-operative period.

Unquestionably the most important pre-operative procedure is the transfusion of blood, at least 2 transfusions of 750 to 800 cubic centimeters each being required. Following this treatment, the direct beneficial effect is apparent by improved appearance in the general condition of the patient and the lowered coagulation time of the blood.

The factor of dehydration must also be borne in mind. This can be remedied by the use of a 10 per cent solution of glucose in normal saline given either subcutaneously, intravenously or both as necessity dictates. The diet should be rich in carbohydrates. Ordinarily we encourage these patients to eat large quantities of hard candy. It is not within the scope of this paper to discuss the so called liver deaths but Graham's work is strong evidence that the chief factor in the prevention of this catastrophe is an adequate store of glycogen.

In the light of the recent work of Snell and his coworkers estimations of the prothrombin level and the prothrombin time will undoubtedly be added to the pre-operative routine as will the treatment with the newly isolated vitamin K which has a marked effect upon the jaundiced patients who have a deficiency of this substance.

TESTS OF LIVER FUNCTION

The tests of liver function are generally unsatisfactory because the liver has such a large

reserve that even quite marked structural changes do not produce an alteration of function as gauged by the tests now in use. The tests we have used are: (1) bromsulphalein retention in plasma after intravenous injection, (2) galactose tolerance test if jaundice is present, (3) Takata Ara test in blood and in ascitic fluid in the presence of ascites, (4) special blood studies to determine the volume and shape of the red blood cell and the degree of anemia and (5) determination of total blood protein.

The bromsulphalein test is the most sensitive of all tests now in use but it is not satisfactory in the presence of obstructive jaundice. The galactose tolerance test is not a sensitive one and has little practical application in liver disease. The excretion of galactose may be impaired if the jaundice is due to liver disease but the test gives normal findings if the jaundice is due to simple obstruction.

The Takata Ara test is positive in a number of types of liver disease but is most frequently positive in cirrhosis, a negative test being strong evidence against the presence of cirrhosis. If ascites is present and the test is positive in the ascitic fluid, the accumulation of fluid can usually be attributed to cirrhosis. These same observations are true in regard to the determination of the total blood proteins.

If there is liver damage anemia is a common finding. Here the red cell is nearly always larger than normal so a macrocytosis of the red cells is suggestive of disease of the liver parenchyma. If there is obstructive jaundice due to a sease of the bile ducts a flattening of the red cells occurs with out an increase in volume.

The change in the red cells seems to be the most sensitive index of liver function but these studies must be repeated frequently to be of clinical significance. The most useful test is the bromsulphalein test. The Takata Ara test is simply done and may give valuable information.

Surgeons are often confused by the various methods used in determining the coagulation time in severely jaundiced patients. In our experience all stab and puncture methods have been considered to be unreliable due to the fact that the blood has been squeezed through the tissue. For that reason we have discarded all such procedures and use routinely the White and Lee method which requires 5 cubic centimeters of venous blood. 1 cubic centimeter being placed in each of five 8 millimeter tubes. The first tube is tipped at 4 minutes and the others at the same interval. If the coagulation is not complete in 5 to 8 minutes it is considered abnormal, thus giving an actual

accurate coagulation time. A knowledge of the bleeding time has not been of much clinical assistance.

Cholangiography. Cholangiographic studies will undoubtedly come to be recognized as a definite adjunct in the management of a certain number of patients with fistulas and persistent jaundice. A large bibliography has been accumulated on the subject, and Best and Hicken within the past few years have emphasized its use and importance, either as an immediate procedure at the time of operation, or postoperatively when a fistula is present or a T tube is in place. In certain cases there is some question at the time of operation as to the cause of the obstruction. From their studies these writers have shown that an occluded cystic duct may be the cause of the rather high mortality rate and of some of the failures following a cholecystostomy or cholecystogastrostomy in jaundiced patients. It is not indicated, however, as a routine in the uncomplicated cases. If these plates can be taken while the patient is on the operating table and the opaque substance passed into the gastro-intestinal tract without obstruction, the abdomen may be closed with complete assurance of the patency of the common duct. They believe that cholangiography reveals many stones which could not be felt by palpation or direct visualization. In individuals who have had drainage with a T tube or who have a persistent fistula, cholangiography is undoubtedly of great value in showing the presence of the choledochal stones, strictures, or tumors.

Cholecystostomy or cholecystectomy. Cholecystostomy still has a definite place in the handling of deeply jaundiced patients. True it is that the field is limited, but no hesitancy should be shown in doing a cholecystostomy in a severely ill, elderly patient with a rapidly developing jaundice. When a stone has become impacted in the ampulla, the stone may be seen occasionally in a small pouch at the neck of the gall bladder. It is often accompanied by acute inflammation of the surrounding area, acute cholangitis, and an empyema of the gall bladder. In several such cases the removal of the stone and cholecystostomy have been life-saving measures. Likewise, in a severely ill patient with jaundice and stones in the common duct and the gall bladder, it may be unwise to perform a cholecystectomy instead of draining both the gall bladder and the common duct. I believe that it is a dangerous dictum to state that a cholecystectomy is always indicated. One of the striking features about some of these cases is a marked thickening and edema of the serosa of the gall bladder. For many years one of my asso-

ciates, Dr. William E. Lower, has used a modified cholecystectomy in this group of cases. After opening the dome of the gall bladder and removing the stones, a line of cleavage between the serosa and the mucosa is easily delineated and the mucosal surface stripped out, which at times looks almost like a cast of the gall bladder. This procedure in the proper case has the advantage of being done quickly without leaving a raw, bleeding surface on the liver bed. Dr. Lower has never been obliged to do a secondary operation on any of these patients, and he is favorably impressed by the little postoperative reaction which these patients experience.

The indications for cholecystectomy are well understood. The operation in the deeply jaundiced patient depends upon the local inflammatory reaction and the general condition of the patient. Most surgeons agree that the best type of drainage, after removal of the stones in the common duct, is secured with a T tube, the limbs of which have been shortened and a notch placed on the posterior side so that it can be removed easily. This has been far more satisfactory than the insertion of a straight catheter toward the liver, attempting to sew it and hold it in place with sutures. Undoubtedly these catheters have, on occasion, unknowingly been inserted in the distal side. It is also much easier to approximate the duct accurately about the T tube than around a straight catheter.

The short-circuit operations of the gall bladder to the stomach or duodenum, on the whole, have been unsatisfactory. If possible, it is preferable to anastomose the gall bladder to the duodenum rather than to the stomach. If the anastomosis functions properly, it often gives relief from the intolerable itching of which the patients complain, and quite frequently immediate relief is secured from the deep, boring pain which the patient with a chronic pancreatitis or carcinoma of the pancreas experiences. The opening need be only a small one, and in the deeply jaundiced patients we have felt that silk may be used to advantage on the serosal surface. In doing the operation it is a great comfort to see colored bile returning from the gall bladder after the thick tenacious material has been evacuated. Often-times it is difficult in some of these cases, even with adequate exposure, to know whether you are dealing with an inflammatory or a neoplastic process.

Best and Hicken have pointed out that the high mortality in these patients has been due to the obstruction caused by the inflammation, neoplasm, or stone which has been overlooked, and

this of course is a forceful argument for the use of cholangiography while the patient is on the table

OPERATIVE PROCEDURE

I feel that in my own hands gas oxygen anesthesia augmented by ether has been most satisfactory. We are concerned with an anesthetic which can be given with a minimum of damage to the liver and at the same time give adequate relaxation. Any type of deep anesthesia particularly with severely jaundiced patients, is to be avoided. I have used spinal anesthesia occasionally but still prefer not to use it in the upper abdomen although it may be of advantage in secondary operations upon the common duct.

Incisions for gall bladder work are largely a matter of choice. It is always interesting to note that most surgeons, after trying all the different approaches usually return to the right rectus incision. In this connection one point has been a particular help to me and that is in being careful that the incision is high enough. Dr. Judd always placed particular emphasis upon the importance of carrying the incision as near the costal border as possible. In general it can be stated that surgery of the deeply jaundiced patient is for the most part difficult. Lord Moynihan stated that the surgery of cholelithiasis as a general problem was difficult sometimes extremely difficult and he held it to be of greater technical difficulty and to present more problems for accuracy of judgment than any other branch of surgery. This is particularly true in the obstructive case of jaundice which is either persistent or has occurred after a surgical procedure. One always hopes that it is due to stones in the duct and not to a stricture or injured duct. A great deal of emphasis has been placed on the various types of anastomoses either on repair of the duct or its anastomosis to the gastro intestinal tract. Little emphasis has been placed on the isolation of the structures with which to do an anastomosis. After all the great difficulty is in finding the proximal side of the injured duct. Unquestionably the ideal procedure is to anastomose this to the duodenum and not attempt any plastic surgery on the duct itself.

POSTOPERATIVE CARE

From this discussion it is quite evident that the pre-operative care of these patients is of primary importance if they are to have a smooth post-operative convalescence and avoid the complications so common in the unprepared jaundiced patient. There are a few points that may be mentioned about these patients after operation. It is
